94. **Treatment of Burns.**—Beck believes in keeping the surface moist to promote secretion and elimination. This renders disinfection of the burned area superfluous. He cuts off the blister epidermis and places the patient in a tepid bath for from five to thirty minutes. He is then returned to bed and the burned area is covered with several thicknesses of gauze dipped in a 1 to 4,000 or 3,000 solution of potassium permanganate, with rubber tissue or oiled silk over this. Every thirty minutes the impermeable covering is raised and fresh tepid permanganate solution is poured on the gauze, which is otherwise left undisturbed. When the general condition permits, he has the patient placed twice a day in a large bath tub of tepid water in which about 6 or 8 gm. of the permanganate has been dissolved. The dressing is not removed beforehand; it comes off of itself in the water. The patient is left in the bath for thirty or forty minutes if the heart permits. Beck gives heart tonics as needed and supplies fluids copiously internally. In the severe cases he allows no food but milk in small, frequent amounts. This treatment with wet dressings is kept up until the temperature is normal or nearly normal and the general condition manifestly improved. Then the area is treated with salve to hasten the healing.

95. **Conservative Treatment of Scarlatinal Abscesses.**—Sörensen states that an abscess developed near the ear in fifty-three of the 4,000 scarlet-fever patients at the Copenhagen Hospital. Treatment was by incision down to the bone, drainage, and rinsing out, with or without instillation of dilute iodin-potassium iodid solution and a cotton dressing. Of the fifty-two children treated in this way—fifty-seven abscesses—none died, although the scarlet fever in these cases had been of an unusually severe type and there were numerous other complications. In 100 cases at another institution in which radical operative treatment was applied, the mortality was 9 per cent. The general condition was good in 88.5 per cent. of Sörensen's cases with conservative treatment. The details of the more typical cases are given. Only three of the total number required a radical operation later.

107 Changes in the Myocardium in Epinephrin Poisoning. N. Anitschkow.

104. **Changes in the Hypophysis in Diphtheria.**—Creutzfeldt and Koch find that the circulation frequently fails in diphtheria before there are any clinical signs of change in the heart, and that on autopsy the heart lesions are frequently insufficient to account for the severe atony of the vascular system. They believe that the hypophysis is partly responsible for this atony, and their belief is confirmed by the marked rise in blood-pressure brought about by hypophysis extract. In seven cases of death from heart involvement in diphtheria, they found profound changes in the pars intermedia of the hypophysis. These same changes were produced in guinea-pigs by the injection of pure cultures of diphtheria bacilli. A combined epinephrin-hypophysis extract therapy should be used in cases of diphtheritic heart involvement.

111 *Aseptic Means to Introduce Hand into Uterus. (Vorrichtung zur aseptischen Einführung der Hand in den Uterus.) R. Roosen.
112 *Torsion of Myomatous Uterus. H. Poth.

109. **Cure of Uterine Cancer by Exploratory Curetting.**—In the case to which Stratz refers, the exploratory curetting in

1886 revealed cancer but for six or eight years there were no further signs of cancer on repeated exploratory curetting, done every two years at the patient's request. The curet finally revealed microscopic cancer and vaginal hysterectomy followed at once, but not a trace of cancer could be discovered in the uterus. It seems evident that on both occasions the curet accidentally happened to remove all the cancer cells there were. In the similar case recently reported by Hess, with no sign of recurrence during the five years to date, hysterectomy may yet become necessary.

111. **Aseptic Means to Introduce the Hand into the Uterus.**—An open bag of rubber and an outer open bag of linen are both fastened to a wire ring about 10 cm. in diameter. The hand grasps the rubber bag inside the linen and the linen is drawn back over the hand like a cuff while the ring catches at the vulva and the hand pushes up the rubber bag inside and finally works through it as the cervix is reached. The surface of the rubber bag does not come in contact with the vulva at all, and the hand does not emerge from the bags until just ready to enter the uterus. An illustration of the contrivance is given.

112. **Torsion of Myomatous Uterus.**—In Poth's case a virgin of 56 had known for twenty-one years that she had a pelvic tumor, but as it had caused no disturbance she did not heed her doctor's advice to have it out. Five years after the menopause her abdomen began to enlarge and suddenly symptoms as of acute peritonitis developed. The pains increased after two days and the objective findings suggested torsion of an ovarian tumor but the uterus was found to be the organ involved. There was one quite large and two small myomas; the whole uterus weighed 3,750 gm. and it had twisted completely around. Poth knows of only eighty-two cases of the kind on record; in Kynoch's case the myomatous uterus weighed over 16 pounds and had twisted two and a half times around.

114. **Prostatectomy.**—Prostatectomy is a comparatively rare operation in Italy, and Cimino lauds its advantages, particularly when it is done by Freyer's technic and the cavity left is tamponed with strips of gauze drawn with a thread through a Freyer-Marion tube. He operates with the bladder empty.

116. **The Sugar in the Blood with Kidney Disease.**—Farini tabulates the findings in twenty patients with high blood-pressure. Ten had kidney disease and ten had pronounced arteriosclerosis. Some of the nephritic patients had an abnormally large proportion of sugar in the blood but others did not, and none of the arteriosclerotics had more than the normal proportion.

120 Tests for Pancreas Functioning. (Osservazioni cliniche sulla ricerca del succo pancreatico nell'intestino.) G. Piantoni.

117. **Palpation of the Epigastrium in Diagnosis of Stomach Disease.**—Alessandrini remarks that in the present enthusiasm for laboratory and biologic tests, we must not overlook the importance of palpation of the stomach. This alone may reveal trouble below, and careful palpation of the epigastrium should never be neglected in case of pain connected with digestion. In a case reported, a man of 59 for eighteen months had had oppression and pain in the epigastrium three or four hours after meals, relieved by an alkali. There was no free acid, no vomiting, eructation or black stools, but palpation revealed a very small tumor in the epigastrium on the median line. The tumor became extremely painful to touch during the attacks of pain in the stomach, and during exercise. Roth has reported the case of a patient with a similar syndrome who for seven years had wandered from doctor to doctor taking courses of treatment for gastric ulcer or gastric neurosis, until finally the discovery of a minute hernia on the median line in the epigastrium cleared up the diagnosis and its removal put an end to all disturbances. In Alessandrini's case the hernia was accompanied by a gastric ulcer and the two were removed together. He thinks they were of independent development but that the hernia became painful only after the ulceration had occurred, while possibly the course of the ulcer may have been aggravated by the coexisting hernia.

118. **Ankylosis of the Spine.**—Magnini reviews the cases on record of rhizomelic spondylosis and reports a typical case from his own experience. The patient was a man of 34 and the first symptoms of his trouble had been noticed at the age of 12. After five years of gradually increasing stiffness of parts of the spine, a period followed with pain at these points and also in other joints in which the osseous surfaces are united by elastic fibrocartilages or they have a capsule with synovial lining. Thus the vertebral bodies, shoulder, knee, sternoclavicular and temporomandibular articulations were the ones involved. Study of his case and those on record has revealed certain common features which suggest that the trouble is the result of abnormal function of the glands with an internal secretion, and hence that organotherapy has some prospects of success if given in time before irreparable lesions are installed. He thinks that thymus extract seems most promising. Surgical and orthopedic measures have never given more than temporary relief, confirming the assumption of a constitutional cause.

123. **Suture of Stab Wounds of the Heart.**—Since the suturing of wounds of the heart has become a common procedure, the mortality from such wounds has fallen from 85 per cent. in 1867 to 57 or 53 per cent. in the last few years. Drosdoff has collected 222 cases of cardiac wounds that have been treated by suturing, and 105 of the patients recovered. As the symptoms of stab wounds of the heart are not always clear, the subjective symptoms (general condition of the patient, dizziness, pain in the chest, cerebral manifestations), and the objective signs (hemorrhage, presence of a wound in the chest in the cardiac region, increased cardiac dulness caused by effusion of blood, and abnormal murmurs) being very inconstant, Drosdoff prefers to operate even when there

is a mere suspicion of injury of the heart, though a presumptive diagnosis can generally be made from a combination of different symptoms. In a large St. Petersburg hospital the diagnosis was made in eleven out of twenty-one cases. The operation consists in enlargement of the wound in the chest, resection of the corresponding ribs and, while the heart is fixed by the finger—which may also help to check the hemorrhage—a silk thread is passed through the epicardium and heart muscle, without waiting for diastole or systole. The suture thread must not be tied too tight. The pericardial wound he advises to leave open and tampon; this helps also in draining. If the wound in the pericardium is too large, a couple of stitches are advisable in addition to the tampon. The beneficial results are sometimes striking, no complications in the form of irregular heart action, or pericardial adhesions occurring, as Drosdoff's case shows.

124. **The Wassermann Test in Cadavers.**—Abrikosoff studied the Wassermann test on cadavers and reports the results of 104 tests. Of these 104 cases ninety-two belonged to different non-syphilitic diseases, such as tumors, diphtheria, kidney and liver troubles, etc., and in all these cases the reaction was negative. In the other twelve cases, two belonged to scarlet fever which gave a positive Wassermann reaction with a nonspecific antigen (heart of a guinea-pig); the balance of ten showed syphilis either in the history, or in the pathologic changes of the tissues. The tested fluid was either the blood from the right heart and vena cava, or from the pericardium. The amount was 0.2 c.c. As antigen, an alcoholic extract of a syphilitic liver was used, or Landsteiner's antigen (heart of guinea-pig). Abrikosoff comes to the conclusion that the Wassermann test may be of great help to the pathologist in those cases in which a correct pathological diagnosis cannot be made, for instance, in cases of suspicious arteriosclerosis, aortic changes, chronic renal or liver lesions, etc.

126. **Municipal Measures for the Campaign Against Tuberculosis.**—Fuchs-Volfring discusses in this second article the advantages of specific treatment of tuberculosis as compared with the usual sanatorium treatment which, in his opinion, has given in Germany but meager results. (His first article on the subject was abstracted in The Journal, June 21, 1913, p. 1988.) The public sanatoriums as run at present in Germany, that is, admitting only the early, mild, curable cases, he regards as an anachronism and absurdity, but nobody there is bold enough to express such a view after the hundreds of thousands that have been spent on the sanatoriums. All the patients could have been given specific treatment in dispensaries without stopping their occupation, and a far larger proportion of patients and the 7,000,000 marks could have been thus saved, or the places in the sanatoriums filled by the patients with early tuberculosis could have been taken by 36,000 spreaders of infection. He is convinced that with specific treatment in dispensaries 60 per cent. of those given treatment in the German sanatoriums could have been cured, instead of the mere 20 per cent. of cures that were realized.

127. **Significance of Urobilin in the Urine.**—Kamsarakan has been studying Ehrlich's benzaldehyd reaction indicating the presence of urobilin or urobilinogen in the urine. To 8 or 10 c.c. of urine are added five or seven drops of 2 per cent. solution of paradimethylaminobenzaldehyd. A cherry color indicates a strong positive reaction; a pink color turning red on heating indicates a mild reaction. Altogether 518 patients were examined, with results as follows: In 155 cases of scarlet fever, the reaction was positive in all; in eighty-four cases of diphtheria a positive result was obtained in fifty-one, and in all these cases there was a mixed streptococcus infection; in the rest (thirty-three cases), in which pure cultures of diphtheria bacilli were obtained, or mixed with staphylococci, the result was negative; of 101 cases of various forms of angina, seventy gave a positive reaction, and in these seventy cases streptococci were found. In the rest of the cases, in all of which staphylococci were found, the reaction was constantly negative. In 183 cases of erysipelas—a strictly streptococcus affection—the patients all gave a positive reaction, while in pneumonia (initial stage), typhoid fever, chicken-pox, mumps and measles the test proved negative or inconstant as also in tuberculosis.

As a rule the reaction seems to be positive in all streptococcus infections and it indicates functional insufficiency of the liver. Derangement of the liver is the cause of the urobilinuria or urobilinogenuria—which is practically the same—as the diseased liver cannot transform the urobilinogen formed in the intestines from the bilirubin and biliverdin of the bile. Therefore the urobilinogen passes into the blood and reaches the kidneys which eliminate this substance with the urine. In all diseases in which the liver is directly involved, as in streptococcus infections, pernicious anemia, etc., the reaction is positive, but shortly before death it becomes negative. Therefore Kamsarakan considers the Ehrlich test important not only for the diagnosis, but also for the prognosis. (For other communications on this test see The Journal, May 31, 1913, p. 1750; May 18, 1912, p. 1538, or July 22, 1911, p. 346.)

Simon regards the test as very important for differentiating organic abdominal disease from merely nervous disturbances. In a recent case a young man for years had had trouble indicating hyperacidity, and there was always a strong positive response to the test for urobilinogen. The symptoms became so severe that the patient clamored for an operation and an old duodenal ulcer was found. In two other cases of hyperacidity causing trouble the intense reaction to the test for urobilinogen proved to be a manifestation or consequence of gall-stone trouble. He adds that the simple and easy technic for the test can be applied so readily, even at the office, that he commends it for general adoption in case of doubt whether the gastric symptoms observed are of purely nervous origin or are the work of some organic affection. (Simon's article appeared in the *Med. Klinik*, 1913, ix, 1164.)

129. **Polyneuritis After Salvarsan.**—Solomin's patient received one injection of neosalvarsan and two injections of salvarsan in the usual doses, but all within three days. About four weeks later polyneuritis developed, first in the lower limbs, and then in the arms. The course was progressively subacute; finally slow improvement set in under the usual measures, massage, electricity, baths, etc. The clinical picture, typical for arsenical polyneuritis, the slow recovery without any specific treatment, such as mercury or salvarsan, indicate the etiology of the trouble in Solomin's case in the drugs administered. The patient had been treated long before she came under Solomin's care with plain injections of arsenic which, however, did not cause any bad effects, as compared with those from the salvarsan.

130. **Serodiagnosis of Echinococcus Disease.**—The serum of patients with echinococcus deviates the complement, which Abrikosoff could prove on five patients through subsequent operations. As an antigen the fluid from the echinococcus cyst was used, this being the only variation of Wassermann's test. The echinococcus fluid may be obtained from sheep, beef or men, the best being the sheep's fluid, but that of beef being the most available. The fluid is kept on ice in small sealed tubes, and keeps perfectly for three months. The dose of the fluid is 0.5—1 to 5 c.c. of the mixture. The dose of the patient's serum is 0.2 to 0.6 c.c., the average and sufficient amount being 0.4 c.c. Altogether the blood of thirty-one patients was tested, and all but five proved negative, and in these five the operation showed the presence of the echinococcus. Therefore, deviation of complement with specific echinococcus antigen speaks for echinococcus, and *vice versa*. Sometimes a negative reaction before the operation turns positive after the operation.

138 *Treatment of Burns. (Om Forbrændinger behandelte efter Rovsings Metode.) O. Wulff.

133. **Transplantation of Femur.**—In 1909 Rovsing implanted a stretch of the patient's own fibula in the place of a stretch of the humerus in a man of 26. The bone healed perfectly in place and complete function was restored, but after about a year, in lifting a comparatively slight weight, the fibula fractured, showing that this bone is not strong enough to stand much strain. In a more recent case a woman of 25 required resection of the lower part of the femur; in both cases the bone had been the seat of a sarcoma. In this latest case he implanted at once a segment of an old humerus to keep the stumps apart until the danger of local recurrence had passed. Two months later he had to amputate the leg of a girl of 14 with myelitis and spastic paralysis of the legs. The thigh was amputated between the upper and middle thirds, and Rovsing left the rest of the operation to others while he, on another table, dissected out the femur, wrapped it in napkins dipped in warm salt solution, wrapping it further in oiled silk and then placing it in a metal box and speeding with it in an auto to the other clinic where the patient was already prepared for the implantation, so that he could begin it at once, only twenty minutes after the beginning of the amputation operation. The old humerus implant was removed; the periosteum on the lower end of the femur was loosened and about 2 cm. sawed off, which was also done for 1 cm. on the tibia. Both bones looked healthy. The limb was then stretched and the implant cut to fit the gap of 14 cm., each end being cut with a point to fit into the stumps. It was further fastened with four aluminum-bronze sutures. The patella was removed. A year has passed since the first operation and there has been no recurrence of the sarcoma. There is still a minute fistula where the drain tube had lain, but otherwise the results have been extremely satisfactory. The patient still wears a leather bandage and walks with two canes, but has long resumed her office work. Roentgenoscopy shows the implant solidly fastened in place with good callus at both ends.

134. **Ileus with Congenital Malposition of the Large Intestine.**—Rovsing reports two cases; in the first the woman had had no trouble from this retroposition of the colon until ileus suddenly developed at the age of 20. The operation showed the colon lay behind instead of in front of the small intestine, passing through an opening in its mesentery. In another case the anomaly caused no disturbance until the first pregnancy.

135. **Treatment of Arthritis with Petrolatum Injections.**—Nine years ago Rovsing called attention to the fine results he had obtained in two cases of traumatic arthritis in the hip joint in which he had injected yellow vaselin, curing at one stroke the chronic disturbances. He here states that the cure has been permanent during the eleven and nine years since to date, and describes his further experience with forty-four other patients, eight requiring injections on both sides. This experience, he declares, has confirmed the efficacy of the measure, realizing his highest anticipations. The aim is to supply a lubricant when the natural lubricant, the synovia, is missing on account of the degeneration or cicatrization of the synovial membrane. The method is therefore applicable only in simple dry synovitis or senile joint affections in which the synovial membrane has lost its secreting power. Another indication for the method—and he reports eight cases to illustrate its advantages—is when the vaselin is injected to prevent development of ankylosis after incision or resection of the joint. This group of cases shows that injection of vaselin can successfully prevent ankylosis after resection of a tuberculous joint process, when all the diseased tissue can be removed. Also when there is no infection and hence no need of drainage. When puncture shows that there is fluid present in the joint, of course injection of vaselin is superfluous and may do great harm, but in appropriate cases his success has been remarkable. One young man of 22, a sailor, had had trouble in his right hip joint since the age of 9 when this region had been injured in a wagon accident. The joint had long been painful and the neighboring muscles were atrophied. The capsule was punctured with a trocar through an incision 5 cm. long above the greater trochanter. No synovial fluid could be detected, and at once 25 c.c. of yellow vaselin was injected. The relief was immediate, complete and permanent so that six days later the man passed a severe examination for the position of able-bodied marine and did his work without disturbance of any kind, no one suspecting the previous joint trouble until the navy surgeon several months later accidentally discovered the little scar left from the operation. (Rovsing's previous communication on the subject, giving the details of the first two cases mentioned above, was summarized in The Journal, April 29, 1905, p. 1412.)

He uses a tube with metal cap which screws on the collapsible tube of vaselin, and boils the whole for fifteen minutes before the injection. The only dangers are embolism and infection. The former is prevented by using a blunt-pointed cannula and being sure that no blood escapes from it and that the point moves freely in the joint before the cannula is screwed to the 10 cm. long rubber tube connected with the vaselin. The amount of vaselin to be injected seems to be about 20 or 25 c.c. for the hip joint; not over 10, 12 or 15 c.c. for the knee; 15 c.c. for the shoulder.

136. **Leukoplakia in the Bladder.**—Lendorf's patient was a man of 66 who had signs of chronic cystitis and for ten years had occasionally passed in his urine cells of epidermis in horny degeneration. The cystoscope showed a patch of leukoplakia in the bladder. He was treated as for ordinary cystitis and refused operative measures. Lendorf knows of only thirty-one cases of leukoplakia vesicae in the literature. The symptoms are those of chronic pyuria with cystitis, probably a vicious circle.

138. **Treatment of Burns.**—Wulff reviews the experiences with sixty cases of severe burns treated by Rovsing's method. The main features of the method are that the region around is sterilized and then, under a few whiffs of ether, the burned area is cleansed with soap, alcohol and a mild antiseptic. The burned area is then covered with rubber tissue in which numerous small holes have been cut. The rubber tissue extends about a quarter of an inch beyond the edges of the burn, and above the rubber tissue is spread a layer of 1 per cent. silver nitrate gauze, dry, and above this again dry absorbent cotton, the whole held in place with a gauze bandage. This local treatment is supplemented with narcotics, stimulants and saline infusion as indicated. Under this treatment no contracture developed in any case. The secretions escape around the edges or through the holes and are absorbed by the medicated gauze and the area heals over in an almost ideal manner. In one case a young man had been extensively scalded with steam; this treatment was applied almost immediately and the burn had entirely healed by the seventeenth day. In another very similar case three days elapsed before this treatment was begun, and the burn was already suppurating profusely. Sixty-seven days were required in this case before healing was complete. In six fatal cases in which the urine had been examined, albuminuria was noted in all but one, while there was albuminuria in only two of the forty-nine patients who recovered (among those whose urine had been examined), and the albuminuria was very slight. Wulff thinks that examination of the urine is important for the prognosis of burns. As only the severest burns were admitted to the hospital, the eleven fatalities in the sixty cases he regards as a good record. No report is made on the numerous other cases of burns in out-patients.

CHRONIC FOCAL INFECTION AS A CAUSATIVE FACTOR IN CHRONIC ARTHRITIS *

FRANK BILLINGS, M.D.
CHICAGO

I presented a paper[1] on this subject in January, 1912. The study of the subject has been vigorously carried on since that date. Altogether seventy patients suffering from arthritis deformans have been investigated and treated in the Presbyterian Hospital under the auspices of the Otho S. A. Sprague Institute and the Dane Billings Memorial Fellowship in the Department of Medicine of Rush Medical College.

This clinical research has confirmed the principles announced in the first paper. It has been found that the focal disease was usually located in the head. Most frequently this was a chronic streptococcus focus of the faucial tonsils; but chronic alveolar abscess and chronic sinusitis due to streptococcus infection were an occasional cause. In monarticular osteo-arthritis of the hip especially, chronic hypertrophic prostatitis with residual urine, chronic cystitis and infection with the colon bacillus seemed to be an etiologic factor. There can be no question that chronic gonorrheal infection of the seminal vesicles may cause systemic disease, especially arthritis. Streptococcus infection of the seminal vesicles may also cause systemic infection and especially arthritis deformans.

In this work the chronic focus of infection has been located in the faucial tonsils, dental alveoli or jaw, the antra of the head and in the seminal vesicles and prostate gland.

Rationally one may find the septic focus in any circumscribed streptococcus abscess, possibly a chronic appendicitis, chronic cholecystitis, etc.

The patients who were the subjects of this investigation were from the various walks of life. All were adults. Three patients over 50 years of age suffered from monarticular osteo-arthritis of the hip (morbus coxae senilis). All of the remainder presented the three prevailing types of chronic arthritis with deformities; that is, the so-called proliferative or hypertrophic; the degenerative or atrophic; and the spondylitis deformans type.

The study of these patients shows that an individual who suffers from what may be called a true arthritis deformans presents not only an arthritis (periarthritis, synovitis or osteo-arthritis may be present in different joints of the same patient), but also a chronic myositis which is more or less selective. The muscles most often involved are the biceps humeri, the masseters, the erector spinae, the anterior tibial group and the hamstring muscles. This is a chronic not very painful myositis which causes shortening of the muscular fibers. Hence the inability of most of these patients to extend the forearm fully. Many cannot fully open the mouth because of the contracted masseter muscles. Some rigid spines are due to muscular contraction and rigidity and not to involvement of the joints of the vertebrae.

Most of these patients present evidence of chronic neuritis or perineuritis of single or multiple nerves, at some time in the course of the disease.

Practically all of these patients suffer from general debility; anemia of various degrees, loss of weight, lessened strength and endurance, and functional nervous disorders. Long suffering intensifies the perception of pain and other discomforts.

There can also be no question that a faulty metabolism modifies the whole morbid process. If one considers the results of the treatment carried out in this investigation, it would seem that the faulty metabolism is not a primary factor etiologically. Nevertheless, it is an important factor in the progress of the disease and also in its treatment.

The severe trophic disturbances which occur in the joints (cartilage, bone, etc.), the appendages of the skin (nails, hair, sweat-glands), are difficult to explain. One does not find cerebrospinal or peripheral nerve lesions to account for these changes as in tabes dorsalis (Charcot joint) or other neuropathic conditions. Probably the primary cause is the tissue reaction to the bacterial toxin, and this specifically excites a proliferative or degenerative local metabolism with the characteristic morbid anatomy. In the experimental inoculation of rabbits with a strain of streptococcus obtained from arthritis patients by Dr. D. J. Davis[2] and Dr. Leila Jackson,[3] non-suppurative, proliferative and degenerative joint lesions were produced. From the joint tissues the same organism was recovered. There is, therefore, a strain of the streptococcus which will specifically produce in the inoculated rabbit morbid anatomic lesions, which resemble the morbid joint changes in arthritis deformans in man.

The method of procedure in this investigation was the same as that described in the former paper. From each patient a most thorough clinical history was obtained. A careful general and special examination was made. When necessary clinical aid was obtained from throat specialists, urologists and other special

experts. When found the focal infection was removed surgically or otherwise. Plate-cultures of the material were made from the abscesses or exudate of the operated tissues. Subcultures were made from the dominant bacterial colonies of the plates. The opsonic and phagocytic indexes of the blood of the patient with the dominant bacteria were studied before and after autogenous vaccination at intervals of one week. Rabbits were inoculated with the living bacteria, and the results studied on the animal living and dead.

These bacterial studies have revealed some notable results. The dominant organism found in abscesses and sealed crypts of the faucial tonsil are *Streptococcus viridans* and *Streptococcus hemolyticus* (*pyogenes*). The *S. viridans* is usually a surface growth, while the *S. hemolyticus* is frequently found in pure culture in the deeper infected tissues. In acute rheumatism the bacteria obtained from joint exudate and from rheumatic nodes have been studied by Dr. Edward C. Rosenow, fellow of the Memorial Institute for Infectious Diseases, cooperating with us. He has found that organisms from rheumatism appear to occupy a position between *S. viridans* and *S. hemolyticus*. They are more virulent than the former and less virulent than the latter. Three types of organisms have been isolated from rheumatism. One type produces green on blood-agar and forms very long chains. The second type produces a narrow zone of hemolysis on blood-agar from the beginning or after several generations and forms short chains. The third type produces a grayish-brown colony without affecting perceptibly the blood in the media and appears as a diplococcus in short chains and as single cocci. By varying the condition of growth, these types may be changed quite readily, one into the other. The most distinctive cultural features are their production of a very high acid reaction in dextrose broth and abundant growth at a low temperature. They are more virulent to warm-blooded animals than *S. viridans*, but less virulent than *S. hemolyticus* and, of course, the pneumococcus. To frogs at 22 C. (71.6 F.) the virulence of the rheumatism strains is, however, greater than both the *S. hemolyticus* and the pneumococcus; but if the frogs are kept at 37 C. (98.6 F.) the order of virulence is the same as in warm-blooded animals.

The cultural features are not so distinctive as the pathogenic properties. The results following injection in animals are quite different from those following injection of *S. viridans*, *S. hemolyticus* and even mixtures of these two strains. It is common to produce by intravenous injection in rabbits, multiple non-suppurative arthritis, endocarditis, myocarditis and pericarditis in the same animal. By modifying these strains by varying culture methods, their affinity for joints, endocardium and pericardium becomes less and the affinity for the muscles, myocardium and kidney much greater, producing now a non-suppurative myositis. The largest number of these lesions is found in the flat muscles of the neck, shoulders and spine, the intercostal muscles and the more tendinous portions of the muscles of the extremities. Three of the strains from rheumatism have been converted into typical pneumococci. Reverse transmutations may be made from the pneumococcus to the various cultural characteristics (green, gray and hemolysis producing streptococci) by varying the culture mediums, oxygen tension, etc. The strains of streptococci studied from various patients are undoubtedly the same as those described by Poynton and Payne and Beattie as the *Micrococcus rheumaticus*. The results of the clinical studies and animal experimentation by Poynton, Payne, Walker, Beattie, Yates, Cole and others have been of great value in establishing the cause of acute articular rheumatism. Confusion has existed in the minds of many because the organisms described by the different investigators did not coincide.

The results of the work of Rosenow seem to adjust the differences, for his experiments show that the same organisms may be changed by cultural methods so that they may in mediums show progressive phases of transmutation. The range of transmutation is from a type of streptococcus to the pneumococcus. Furthermore, at different stages of the transmutation he has, at will, produced in the inoculated rabbit, suppurative arthritis, or at another phase multiple proliferating arthritis, endocarditis, pericarditis and myocarditis, or at another phase myositis of some of the general skeletal muscles, at another phase, a virulent type which produces arthritis with proliferative and degenerative joint lesions, and at another phase typical pneumonia. These experiments probably clear up this difference in results and the varying types of streptococci described by many investigators.

Many investigators have searched for the source of the infectious organisms of chronic arthritis in the alimentary tract. Strains of streptococci isolated from the feces have been used as vaccines in the treatment of chronic arthritis. We have not experimented with the intestinal flora in this investigation.

In the treatment of these patients we have carried out the following plan:

1. All possible sources of focal infection have been removed. Tonsillectomy; oral surgery for alveolar abscesses (roentgenography will show jaw disease); drainage or other measures to cure sinusitis; vasectomy to drain and to use the vas deferens to wash out infected seminal vesicles and to drain the prostate gland, and any other measures necessary to surely remove all possible streptococcus foci of infection have been made use of.

2. The patient's immunity to the infectious organism has been improved by:

(*a*) Absolute rest for an indefinite period. This may be absolute or partial recumbency dependent on the individual and the character of the disease.

(*b*) Improvement of the general and individual hygiene. The patient needs good air, sunshine, good wholesome food with plenty of proteins to replace wasted tissue, restorative tonics when required, plenty of fluid drink and the necessary laxatives. Fatigue must be avoided. Gentle superficial massage may be used, but in the beginning never to the degree of causing pain and fatigue. A cheerful environment and constant moral support are essential to all of these patients who are despondent because of long suffering. Many of them are pessimistic of hopeful results of treatment because baths, superheated-air treatments, massage, osteopathy and drugs have not only failed, but have made the disease worse. These measures modified to meet individual peculiarities will usually improve the general condition, and the immunity to the infectious organism is increased as shown by the steady improvement in the condition of the joints. Indeed, it is my opinion that these measures alone will stop the further progress of the disease, and usually entire recovery will take place; but for some patients this will require a long period of treatment.

(*c*) Autogenous vaccinations with the strains of streptococci isolated in each patient. This practice has been followed in practically all of the patients. Immunologic study of the blood has been made coincidently. As a rule the opsonic index and also the phagocytic index have been increased by these vaccines.

Many of the patients investigated had been ill for months or years. Some of them had received vaccinations of commercial vaccines, single and mixed, and during the past year several had received repeated injections of Rheumo-Phylacogen. As far as could be learned, these treatments were instituted without any investigation of the patient's condition, and without a diagnosis of the infectious micro-organism. Not one of them had received benefit from the vaccines of any kind. Many of them were apparently made worse.

There is a value in vaccine therapy, but to obtain benefit from vaccines, they should be rationally used. To use vaccines, simple or mixed, in the treatment of a patient, without first ascertaining the nature of the disease, and if infectious, the kind of invading organism, is unscientific, reprehensible and wrong. When the mixed vaccines or the filtrate of culture-broth of countless organisms are used, it is like the shotgun prescription of our ancestors of the profession. They were and are intended to hit something. There is this difference between the old and the new shotgun: The abused stomach could reject the old shotgun mixture; the new shotgun mixture is injected subcutaneously or intravenously, and the patient cannot escape it. It is my opinion that vaccine therapy irrationally used and the injection of so-called serums made from culture-broths are usually without benefit to the patient with arthritis deformans and often result harmfully to the health or life of the invalid.

THE USE OF POLYVALENT STREPTOCOCCUS HORSE-SERUM IN CHRONIC ARTHRITIS

In the latter part of 1911 and the early part of 1912, two horses were immunized with approximately thirty strains of streptococci obtained from the foci of infection of the patients suffering from arthritis deformans. This serum was concentrated and refined and after heating was used in approximately twenty-five patients. The serum seemed to intensify the immunizing effects of the autogenous vaccines. In spite of the practice of all known precautions, every patient suffered after the second or third treatment from anaphylaxis. Usually this was manifested as an erythema and urticaria, with intense itching of the skin. There was usually a slight rise of temperature and much discomfort from muscular soreness, aching and joint pain. Three patients, all women, suffered from anaphylactic shock of such severity that they nearly died. Inasmuch as we could not prevent these reactions, by all known precautions, that part of the treatment was abandoned as a measure too dangerous to use. This we did with the conviction that the other measures enumerated before, to improve the immunity of the patient, were practical and sufficient.

When the improvement of the joints and the general condition of the patient permitted, the contracted muscles were stretched under gas anesthesia, and if necessary plaster casts were applied to the lower extremities. At the proper time calisthenics and graduated walking were instituted. Tonic hot-cold spray baths were given daily to some patients.

Hospital treatment is necessary to properly investigate and manage patients with chronic arthritis. Otherwise the necessary discipline, individual hygiene, proper rest and the later application of passive and graduated exercise will not be faithfully carried out.

DIFFERENTIATION OF ARTHRITIS DEFORMANS FROM OTHER TYPES OF CHRONIC ARTHRITIS

Based on these clinical and bacteriologic studies and experiments, I think we may now recognize arthritis deformans as a distinct clinical type. The proliferative and degenerative types of polyarthritis present a subacute or chronic course with exacerbations and remissions, polyarticular arthritis (periarthritis, synovitis, osteo-arthritis), chronic myositis with contractures of muscles and consequent deformities, palpably sore nerve trunks, trophic disturbances of the skin and its appendages, varying degrees of malnutrition and frequently a neurotic condition. Severe and mild degrees of the disease exist. In an early stage recovery may occur and in later stages with serious morbid structural changes the progress may be checked spontaneously. This is explicable when one recalls the fact that the etiologic chronic focus may disappear spontaneously by the development of a process of local immunity.

Chronic gonorrheal arthritis is often deforming and not uncommonly is polyarticular. The knee, ankle, wrist, shoulder and spine are the joints most frequently involved in the order named. Tenosynovitis is a common occurrence in gonorrhea, but myositis practically never. Male adults are more often infected than females. The frequency of gonorrhea in female children makes gonorrheal arthritis more common in girls than in boys. If a careful examination is made the focal gonorrhea can usually be found. In the male the seminal vesicles and prostate are the seat of the focus and in the female the vagina, fallopian tubes and probably the glands of the labia may harbor the organism. The skin anaphylactic test may be used to confirm the diagnosis. The removal of the cause; massage of prostate and vesicles, vasectomy to promote drainage of the vesicles and prostate and to permit the injection of antiseptic remedies into the vesicles through the vas deferens, and the necessary surgical and local treatment of the female genitalia will render the diagnosis absolute by the recovery of the patient.

Chronic tuberculous arthritis is usually monarticular, often suppurative, and begins as an osteomyelitis in the short bones or in the epiphysis of a long bone; there is frequently a tenosynovitis and practically never a chronic myositis. The clinical history is usually very characteristic. Often the bone or joint disease immediately follows trauma of some sort. After a period great improvement or apparent recovery occurs to be followed in a few weeks or months by a return of the joint disease, which then steadily progresses in severity.

Neuropathic joints (Charcot) are always associated with some of the characteristic signs of tabes dorsalis.

Chronic podagra, with the characteristic tophi and selection of the small joints as a rule is easily recognized. Gouty tophi may be present as a coincidence in arthritis deformans.

Senile arthritis with deformities due to Heberden's nodes, and atrophic changes may be difficult to differentiate from the degenerative (atrophic) type of arthritis deformans. The absence of chronic myositis, with contraction of the biceps humeri and masseter muscles and the age of the patient are helpful in differentiation. Senile changes may be coincident in arthritis deformans.

THE RESULT OF THIS METHOD OF TREATMENT

In those patients in whom no marked destruction of tissues has occurred, recovery has taken place in many and others are convalescent. Patients with cartilaginous and bone disease have vastly improved and the progress of the disease has been apparently checked. Case reports are not included for lack of space.

CONCLUSIONS

1. Arthritis deformans is an infectious clinical entity manifesting chronic periarthritis, synovitis, proliferative and degenerative osteo-arthritis, chronic myositis with contraction of muscles and perineuritis or neuritis.

2. Usually coincident but secondary malnutrition and faulty metabolism aggravate the condition of the patient.

3. The infectious source is usually focal and located in the mouth (alveoli), faucial tonsils or antra (sinuses). Occasionally the focus may be in the prostate gland, seminal vesicles, the female genitalia, and probably also in a streptococcus chronic appendicitis or cholecystitis or a circumscribed streptococcus infection anywhere. That the infection may occur from a chronic streptococcus invasion of the intestines is a question to be decided.

4. The morbid anatomy of the experimental chronic arthritis is the same as that found in man. This morbid anatomy is the specific reaction of the infectious organism.

5. Arthritis deformans may be differentiated from other types of chronic arthritis by the characteristic coincident involvement of periarticular and articular structures, chronic myositis, consequent contractions of muscles, secondary trophic changes due to a faulty metabolism, malnutrition, etc.

6. The treatment and management must comprise: 1. The removal of the cause. 2. Improvement of the immunity by rest, personal hygiene, including good food, pure air and sunshine, rational calisthenics and physical culture, moral support and a cheerful environment. Autogenous vaccination may be added to still further improve immunity.

7. The clinical results confirm the principles embodied in this paper.

This investigation has been conducted by a group of workers cooperating with me. Dr. Homer K. Nicoll, the Dane Billings Memorial Fellow in Medicine in Rush Medical College, has made the cultures of bacteria and supervised the immunologic vaccinations and serum inoculations. Dr. D. J. Davis, pathologist at St. Luke's Hospital, has supervised the immunologic studies at that institution. Drs. George E. Shambaugh and S. A. Friedberg have performed the necessary nose and throat examinations and operations. Drs. John Ridlon, A. D. Bevan, Dean Lewis, Carl Davis and C. J. Rowan have given aid when surgical measures (stretching muscles, breaking up adhesions, and applying casts and braces) were required in the treatment.

THE RÔLE OF THE PROSTATE AND SEMINAL VESICLES IN GENERAL TOXEMIAS *

HUGH H. YOUNG, M.D.
BALTIMORE

It is now becoming more and more generally recognized that the etiology of many obscure joint, cardiac, neurologic and other diseases is to be found in chronic infections in remote organs, and in recent years the tonsil, nasopharynx, and alimentary tract have come to be regarded as the frequent site of such infections. The extent to which the genito-urinary tract is to blame has not been appreciated, and in reviewing the literature one finds very few valuable articles giving exact data on this question. Of course, it has long been recognized that gonorrhea, both acute and chronic, is responsible for many general infections, but the part played by the acute and chronic infections of the higher genito-urinary tract, the kidney and bladder, the epididymis and testicle, the prostate and seminal vesicles, has received scant accurate attention.

In this article I shall confine my attention to the rôle of the prostate and seminal vesicles in chronic toxemias and remote infections.

The frequency of acute prostatitis and seminal vesiculitis is well recognized. The fact that in the majority of cases of gonorrhea, the posterior urethra, prostate and vesicles become involved is well known, but I believe that the profession fails to realize, or perhaps neglects the fact that chronic prostatitis and seminal vesiculitis are extremely common diseases, and that they may exist without producing symptoms or attracting the attention of the patient for years, only to show themselves as a danger-seat when the patient marries or becomes the subject of chronic rheumatism or other forms of remote infection and toxemia arising from an old prostatitis or vesiculitis.

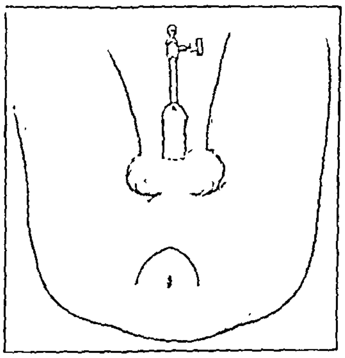

Fig. 1.—Showing the crescentic incision in the skin.

The original etiology of these cases is by no means always gonorrheal. Many arise from bacterial infections which come down through the urinary tract, having been eliminated through the kidneys during acute infections in other parts of the body. I have seen several such cases as a result of typhoid fever, and they are not uncommon in chronic inflammations of the kidney and bladder. Infections also reach the prostate from the rectum not infrequently as a result of proctitis, ulcer, hemorrhoids, etc., but more common still are those which come as a result of the long-continued frequent habit of masturbation, which in many cases produces an extensive chronic inflammatory process involving both the prostate and seminal vesicles and the tissues around them, so that one frequently finds an extensive enlargement and pronounced chronic inflammatory condition associated with local and remote symptoms sometimes of severe character.

The gross pathology of chronic prostatitis and vesiculitis varies so greatly that time precludes my doing more than mentioning the subject here.

On rectal examination often the prostate is very little enlarged, and may be quite smooth, but the surface is generally indurated, often variable in character, slight irregularities being present and adhesions to the rectum and lateral walls of the pelvis usually found. In the majority of cases the seminal vesicles are similarly affected, irregularity, induration and adhesions being the characteristic findings. In more pronounced cases there may be greater enlargement, sometimes very great, very marked induration, and sometimes softening, fluctuation, localized focal abscess, etc., though these are rare. The essential process is an endo-acinous and periacinous inflammation in the prostate and chronic inflammatory infiltration within and about the vasa deferentia and

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

seminal vesicles. Owing to the fact that all these structures drain badly, being dependent on minute tortuous ducts and tubules, foci of chronic inflammatory infiltration remain unrelieved for years, often become surrounded by fibrous changes, and remain centers for the absorption of toxins and infections, and sources of local irritation, pain and discomfort.

It is indeed remarkable that any of these patients ever recover. As a matter of fact, in many chronic inflammations in this region recovery never occurs unless vigorous assistance is given either by the mechanical evacuation afforded by prostatic and vesicular massage or hot rectal douches, or by bacterial therapy or by operation.

SYMPTOMS CLASSIFIED

The results symptomatically of chronic prostatitis and seminal vesiculitis may briefly be classed as local, urinary, sexual, nervous and general.

The local symptoms are often so slight (merely a little discomfort, fulness or heaviness in that region) that it is most often the sexual changes which bring the patient for treatment.

The nervous symptoms are often so remote and disconnected that the prostate is not suspected. I have seen many cases of lumbago, sciatica, vague pains in the back, hips, thighs, perineum, groin, and often as far as the soles of the feet, caused by chronic inflammations of the prostate and seminal vesicles which by involving nerve terminals cause stimuli to be sent to the spinal cord and there transmitted to other visceral and superficial regions according to the dicta laid down by Head in his explanation of the etiology of referred pains.

I hope I may be pardoned for digressing somewhat to call attention thus to the great importance of examining the prostate in many painful conditions anywhere between the diaphragm and toes, when there are no localizing symptoms to direct attention to the prostate itself. In such cases it is often the site of an extensive chronic inflammatory process which is the cause of the whole trouble. I know of ten cases in which there was operation for renal calculus, the symptoms of which were typical: severe intermittent colicky pain radiating to the groin and associated with symptoms of hematuria and entirely due to a chronic inflammatory process in the prostate and seminal vesicles with reflex referred pains to the kidney region, the blood coming from a congested and inflamed posterior urethra.

It is with the conditions and symptoms resulting from absorption of toxins and bacteria from the prostate and seminal vesicles which it is my particular object to lay stress on, and perhaps I cannot do better than to cite a few cases to bring out some of the different phases of these conditions.

REPORTS OF CASES

Case 1.—G. W. S., aged 31, complained of multiple arthritis of six years' duration following an old urethritis. There were no local prostatic symptoms. The patient was bedridden and reduced to a skeleton; he was unable to walk, use his hands or even his jaws. He voided urine normally, and there was no urethral discharge, but rectal examination showed that while the prostate itself was only slightly enlarged and indurated, there was an extensive plateau of infiltration above it. An operation through the perineum evacuated a great deal of pus with a resulting immediate benefit in joints which had so long been terribly inflamed.

Case 2.—R. L. G. complained of arthritis of left knee and painful heels. The patient had had gonorrhea several years before, and now very slight urethral discharge and no urinary symptoms. Examination showed double Achilles tendon bursitis and exostosis of the os calcis, besides extensive arthritis of the left knee. The prostate and seminal vesicles, which gave forth no symptoms, were enlarged, indurated and adherent, and the secretion obtained from them contained pus. Treatment by rectal massage and intravesical irrigations of nitrate of silver gave good results.

Case 3.—M. S. complained of sciatic rheumatism, pain in back, hips and thighs, and inability to walk without crutches. There were no urinary symptoms and no urethral discharge. The urine was clear and the kidneys negative. Roentgenoscopy revealed exostoses along the spine, and examination of the prostate and seminal vesicles disclosed a chronic inflammatory process, the secretion obtained by massage containing pus in abundance. Under local treatment the patient was soon able to dispense with his crutches and walk, and many of the referred pains had disappeared before plaster jackets were applied for the relief of the spinal exostoses.

Case 4.—J. B. C. complained of severe dull pain in the right iliac fossa of several years' duration. The patient had had gonorrhea twenty-four years previously and four years later he began to suffer pain which had never left him. The appendix had been removed, the kidneys suspended, various abdominal organs examined and the patient had had numerous operations without relief. Examination disclosed a chronic prostatitis and marked seminal vesiculitis on the right side; the nerve terminals being involved in the inflammation and giving rise to the referred pains from which the patient had suffered so long.

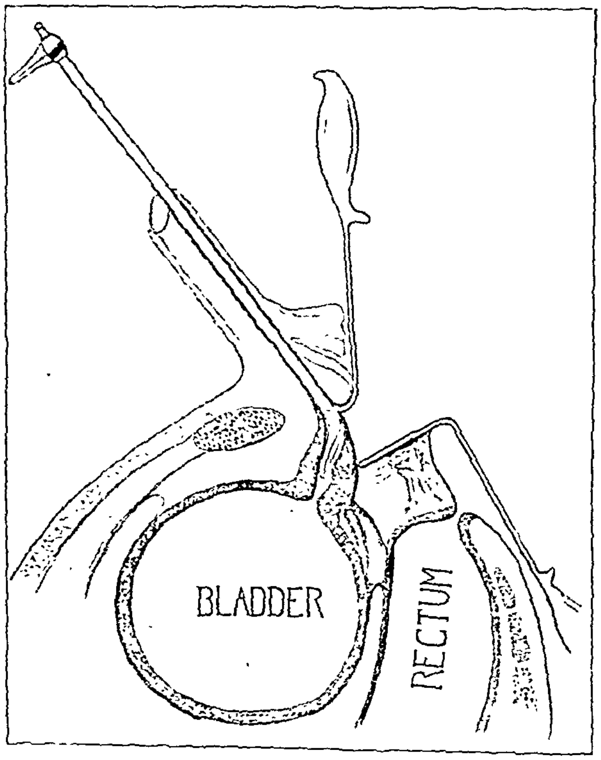

Fig. 2.—The tractor used as a sound in the posterior urethra to show the position of the membranous urethra and apex of the prostate.

Case 5.—G. H. R., aged 63, complained of severe pain in the back and legs of ten years' duration, which often incapacitated him from working. There was no history of gonorrhea. There were also frequency of urination and on coughing a severe pain across the lower abdomen. Examination showed a chronic prostatitis and vesiculitis with an extremely tender point in the middle of the prostatic urethra, and pressure on this was followed by the escape of a calculus from the urethral meatus.

Endoscopic examination showed a very large verumontanum, in the center of which was a cavity from which the calculus had escaped. The symptoms as described persisted regardless of the escape of the calculus until by treatment the prostate, seminal vesicles and verumontanum had been brought to normal. Since then, for several years, the patient has remained entirely well.

Case 6.—S. M. C., aged 58, complained of severe attacks of heart-disease, fever and frequency of urination. The patient was quite well until an attack of acute prostatitis, non-gonorrheal in character, several years previously. Since then evidence of myocarditis and severe organic change in the heart has come on, the condition being aggravated from time to time by temporary increase in the prostatic inflammation. Examination showed a very bad heart, myocarditis, auricular fibrillation characterized by severe attacks of dyspnea and very rapid heart-action. The prostate and seminal vesicles were chronically inflamed; infection by the colon bacillus and a chronic cystitis were present. Prostatectomy and seminal vesiculotomy were indicated but not carried out owing to the severity of the cardiac condition. Under local treatment the condition of the patient improved considerably for a time, but in a few months he died as a result of his heart-disease.

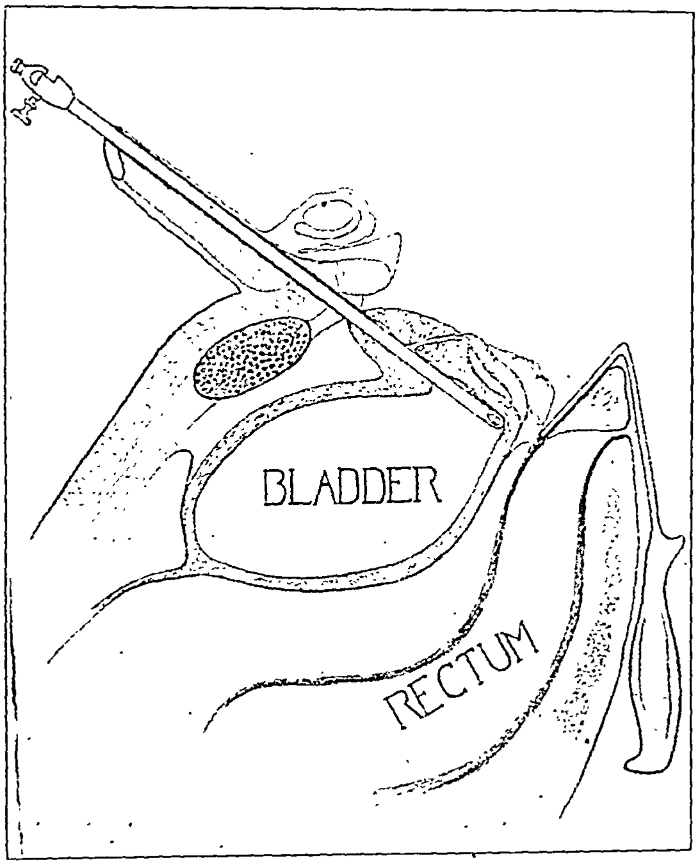

Fig. 3.—Tractor opened out, traction made and seminal vesicles exposed.

Patients with prostatic hypertrophy have in many instances an associated chronic prostatitis and seminal vesiculitis, and I have frequently seen severe joint troubles and neuritis, resulting from these conditions, absolutely relieved by perineal prostatectomy, often to the amazement of the patient at the unexpected cure of an old rheumatic condition from which he had suffered for years.

Glancing at the literature one finds numerous articles on gonorrheal arthritis and other forms of general gonococcus infection, all of which are too well recognized to need more than passing notice here.

Very little is to be found in the literature in regard to the remote infections and toxemias resulting from chronic diseases of the prostate and seminal vesicles.

In a recent report of 254 cases of seminal vesiculotomy performed on account of chronic inflammation of the seminal vesicles, Fuller states that 124 cases, or about 50 per cent., were associated with "absorption or toxic rheumatism," and that all of these cases were relieved in a most radical manner by the operation of vesiculotomy. In his last series of eighty-nine cases, "80 per cent. of the patients were well and free from all symptoms when passed from observation a month or six weeks after operation." One of his patients operated on three years before, after having been on crutches for seven years, is now in perfect physical condition.

Besides the article of Fuller one finds practically nothing in the literature as to the operative treatment of these cases, but numerous rather indefinite articles describing general methods of treatment, particularly by means of vaccines, serums, etc., with some enthusiastic and many unsatisfactory results.

The operation performed by Fuller is so well known that I need not refer to it here. This procedure, which requires such extensive incisions on each side of the buttocks, rectum and perineum and is seemingly so formidable, is shown by Fuller to be free from danger in that he has had no mortality in 254 cases.

An operation which I have been in the habit of carrying out is based on a desire to see the region of the prostate and seminal vesicles, and to be able to proceed thereon as indicated by the pathologic conditions found to be present.

The prostate is exposed in much the same manner as in perineal prostatectomy, the only difference being that instead of a sound in the urethra a long special prostatic tractor, which can be passed through the urethral meatus is employed. The usual inverted V-shaped cutaneous incision starting with the vertex of the V about 1¼ inches in front of the anus, and the two branches paralleling the ischiopubic ramus to a point about an inch to the outside of the anus on each side are used. After the fat and superficial fascia have been penetrated, the fossa on each side of the central perineal tendon bounded in front by the transversus perinei muscle, posteriorly by the levator ani muscle, and externally by the ischiopubic ramus is opened up by blunt dissection with the finger and scalpel. The bifid tractor is then introduced, thus pulling the levator ani backward and putting the central tendon on stretch. With a scalpel this tendon is divided immediately behind the bulb, and deep down the muscular fibers covering the membranous urethra and known as the recto-urethralis muscle are cut, thus allowing the rectum to be pushed back, and the urethra containing the closed long tractor exposed.

Up to this point the procedure has been practically that of perineal prostatectomy. Now instead of incising the membranous urethra, the long tractor is pushed down into the bladder, opened out, traction made, and the posterior surface of the prostate then exposed after separating the rectum from it, the operator being sure that he is in front of Denonvillier's posterior fascia, and working on the shiny capsule of the prostate itself, which is always the guide to show when one is in the proper layer of cleavage in separating the rectum from the prostate. By continued traction and use at the same time of the instrument as a lever by pushing the outer end toward the patient's hip, the prostate is compressed against the triangular ligament and the seminal vesicles are brought up toward the wound where, with good lateral and posterior retraction, any procedure which seems desirable can usually be carried out. Sometimes the adhesions around the seminal vesicles are so extensive that they have to be broken through before good exposure of these structures can be otained, but usually little difficulty is experienced in drawing the seminal vesicles close into the wound. Examination will then show that they are covered by the same transverse layer of fascia as the prostate, the anterior fascia of Denonvillier which forms the true strong capsule of the prostate and also covers transversely the seminal vesicles, vasa deferentia and intervesicular and retrovesical structures, and this must be divided before any of these structures can be attacked.

It is well here to make a careful survey of the site, to see whether the prostate is sufficiently abnormal in any portion to require incision or excision, and the same for one or both seminal vesicles. The vasa deferentia cannot be so easily detected, but after division of the fascia of Denonvillier they can usually be isolated, examined and opened if desired. Examination previous to operation should have shown with considerable accuracy the conditions present, and given an indication of the extent of the procedure which should be carried out; but the extent of the procedure will depend much on what the operator finds with the parts thoroughly exposed, when they can be palpated and explored. If the seminal vesicle is surrounded by considerable adhesions these should be freed as much as possible, and the vesicle either opened by one or more incisions or by removing a portion of its posterior surface. The fact that the seminal vesicle is a complicated structure running up and down in several loops before finally ending in the ejaculatory ducts shows the importance of a thorough drainage in several places if necessary, and I occasionally make several windows in the seminal vesicles thus uncovering the interior and supplying good drainage. Resection or incision to a great extent is usually unnecessary and undesirable, except in tuberculosis for which operation is usually contra-indicated, though easily carried out by this procedure.

The importance of "pus tubes in the male," as shown by Belfield, suggests that it may be found desirable in some cases to open widely the ampullae of the vasa deferentia which are easily discovered after the fascia which covers them and the vesicles is turned to one side by the two longitudinal or one transverse incision, and I am of the impression that much more satisfactory drainage for chronic collections of pus in the vasa deferentia can be obtained by this operation than through operations on the vasa in the groin or scrotum. The method of attack on the prostate itself depends, as remarked above, on the extent of the pathologic process, and should be by incision or excision, single or multiple, every effort being made, of course, to preserve the floor of the urethra and ejaculatory ducts and not to open into the urethra. If the median portion of the prostate is enlarged, indurated and obstructive it may be excised or enucleated from in front of the ejaculatory ducts from one of the lateral incisions in the prostate, but as a rule this is best attacked by the punch operation independently, unless a prostatectomy is desirable, when it will usually be best to employ the regular procedure rather than the method above described.

Fuller advises draining the seminal vesicles for ten days by means of rubber tubes, and his experience has been very extensive. It is certainly important not to remove the tubes or gauze packing too soon, else one is liable to have the external wound close with a recurrence of suppuration in the vesicles and prostate and recrudescence of the rheumatism, etc. The external wound is partly closed by bringing together first the levator ani muscles with single suture of chromicized catgut so as to restore them to their normal position in front of the rectum which they protect against pressure on the gauze or drainage tubes, and partial closure of the skin wound. I now generally bring the tubes and gauze out on one side and close the other completely with a continuous subcutaneous catgut suture.

The operation above described is not difficult, in fact much easier than prostatectomy. The long tractor capable of being passed through the urethra does away with the necessity of the incision of the membranous urethra to introduce the old prostatic tractor and thus avoids a urinary fistula, of even temporary character. The ability to see and palpate the prostate, seminal vesicles and vasa deferentia is, I believe, of prime importance in surgery here as elsewhere.

In conclusion, I may say that the prostate and seminal vesicles are very frequently the site of chronic inflammatory processes which often continue for years, give very few local symptoms and are the insidious cause of remote processes, as a result of absorption of toxins and bacteria, and chronic pains referred to other portions of the body, so that the symptoms produced are generally quite remote and apparently unassociated with the prostate and seminal vesicles. This fact should bring home to all practitioners of medicine the very great importance of rectal examinations as a routine procedure. Since such methods have been enforced at the Johns Hopkins Hospital in the medical department, many obscure and distant maladies have been cleared up and ultimately cured by treatment directed to the original source of disease, the prostate and seminal vesicles.

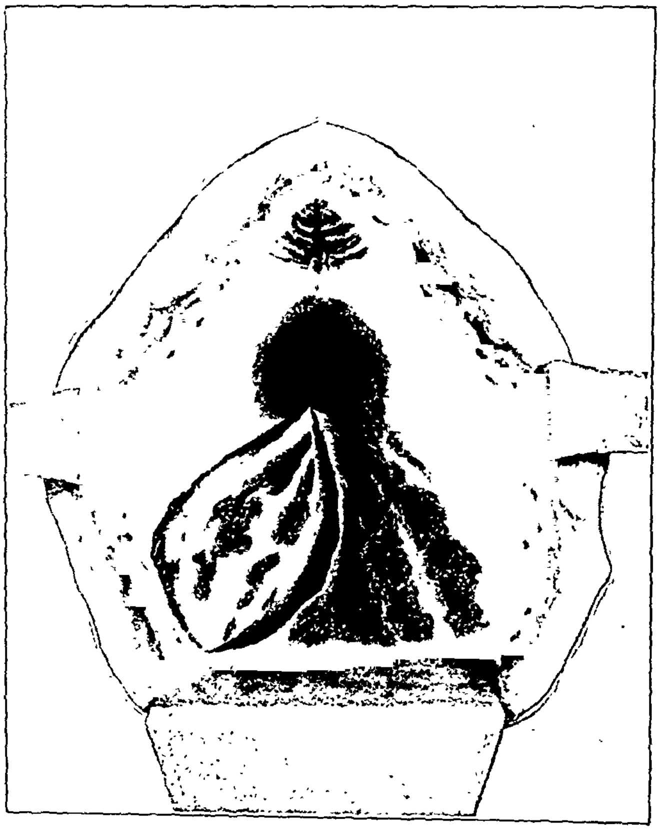

Fig. 4.—Exposure of seminal vesicles. Incision of the fascia of Dénonvillier preparatory to incision or excision of the vesicle.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. BILLINGS AND YOUNG

DR. JOHN RIDLON, Chicago: Is anything to be done for the joint in these cases of chronic non-tuberculous joint disease? What happens if it is not treated? The bone disease usually increases in extent and severity, and finally, after some years, the joint becomes ankylosed; the pain ceases and the patient is comfortable for life. If he chooses that, and you agree, well and good. The joint will not then need any mechanical or surgical treatment. If the patient does not choose that course, then you must choose between mechanical and surgical treatment of this joint. If, perchance, the focus of the disease is found and removed and the disease ceases, the joint will recover and be in as good condition as it ever was so far as function and position are concerned. If not, the deformity will go on, and it is the function of the orthopedist or the general surgeon to prevent the development of the deformity and lessen the pain. These chronic joint inflammations should be treated in the same way as a chronic tuberculous joint is treated, by immobilization and more or less protection for a certain period. So long as there is a tendency to the development of deformity, the joint should be held in the position for greatest comfort and best function and kept immobilized for months or even years. When the patient can stand without pain or discomfort in his immobilization apparatus and when much of the swelling and irritation found locally have disappeared, then I am accustomed to relieve the patient of his immobilization and test out the condition of his joint. Experience is the only guide in choosing the time for this, but there is no need of worrying too much about immobilizing these cases, even if they become ankylosed, because they will become ankylosed whether they are immobilized or not. The point to be remembered is that if the ankylosis occurs, the joint should be in the best possible position. If there is a deformity it can best be corrected at one sitting by force, anesthetizing the patient and then immobilizing the joint until all the soreness resulting from the manipulations has passed. In the case of the hip, the leg should be in slight flexion and the shortening which usually results from destruction of a hip-joint is compensated by a certain degree of abduction. The spine should be straight. The knee should be slightly flexed. In the case of the spine, it should be straightened out and held until it stays in position of itself. This should be done at once, or by repeated applications of force and plaster of Paris, forcing while the plaster is setting. I do not think that such patients should be operated on. The point is, however, that the patient should know that he is the one to choose. He should also know that he may have a good result without an operation.

Dr. Bransford Lewis, St. Louis: In my own experience the posterior urethra is infected in over 90 per cent. of all urethral gonorrheal infections. Of late infections of this kind have been better controlled by the less irritating silver solutions, such as argyrol, nucleinate of silver, and so on; but at the same time, we cannot fail to observe the enormous frequency with which these parts of the tract are infected. Another phase of material importance is the fact that the infection is often not of venereal origin, and therefore apt to be overlooked by one who is not particularly searching in his examination. Even if a patient of this class pass all his urine into two glasses and both are clear, pus that comes from the seminal vesicles may fail to be observed. If you let the patient pass two glasses of clear urine, then massage the prostate and after this have him urinate again, and then find the urine cloudy, containing enormous numbers of pus-cells and possibly numerous gonococci or other microbes, you can determine with certainty as to whether he has seminal vesiculitis. Another point of importance is that in doing the massage of the prostate the patient should be told to place a little butter-platter under the meatus and catch whatever passes out from the urethra. This is subjected to the several steps of examination. By means of massage and heat, irrigations and the use of vaccines we can control these cases better than we used to when we did not have these methods of treatment. In the absence of success with these the operative method is resorted to, and I have used the one described by Dr. Young and found it entirely satisfactory. If only one point is remembered in connection with this subject, it should be that we must detect the focus of infection, which may have persisted for one, ten or fifteen years. By doing so it is possible to clear up a case in which the patient has been a sufferer from a disease which has been beyond the reach of ordinary surgical measures.

Dr. D. N. Eisendrath, Chicago: Not enough emphasis has been laid on the kidney in this symposium. There are so many cases which reach the general practitioner in which there is absolutely no localizing sign pointing to the kidney as the source of the infection. These cases may run along, sometimes for weeks or even months, with a temperature of from 99 to 104 F. and with no evidences of toxemia in the joints, but rather in the body in general. These are the cases that puzzle so many of us, and they are the cases that are so frequently treated and called, for lack of a better name, low typhoid, chronic malaria and cryptogenetic infection. Especially are these the cases in which the patient has been observed for a long time, with low-grade toxic symptoms, and then suddenly the fire flares up, the patient has a temperature of 103 and 104, but still there is no sign of kidney disturbance. Therefore, if we will only consider the kidney—in fact, the urinary tract—in making the differential diagnosis, we shall often clear up a mysterious case, and be able to benefit the patient. It is only by a process of exclusion, by examining the urine carefully, that we can make a correct diagnosis in many cases of chronic joint infections.

THERAPEUTIC PNEUMOTHORAX AS A PALLIATIVE MEASURE, SAFEGUARDED BY STEREOROENTGENOGRAMS

A REPORT OF TWENTY CASES FROM THE CINCINNATI TUBERCULOSIS HOSPITAL *

KENNON DUNHAM, M.D.
Visiting Physician Cincinnati Tuberculosis Hospital
AND
CHARLES S. ROCKHILL, M.D.
Superintendent and Medical Director, Cincinnati Tuberculosis Hospital
CINCINNATI

This paper is not an introduction to artificial pneumothorax or a history of its use or technic. These points have been brought forward with increasing interest and detail since Forlanini's first published suggestion of the value of this treatment in 1882. Murphy, Brauer, Speagler, Saugmann, Schmidt, Lemke, Robinson and Floyd, Weiss, Hamman and Sloan, and many others have added valuable studies to our literature, and it is becoming a recognized method of treatment in some of our more advanced clinics and sanatoriums.

This report of twenty cases treated in the Cincinnati Tuberculosis Hospital and our deductions from the work there is intended to emphasize two things: (1) the value of this treatment as a palliative measure, and (2) the value, almost the necessity, of safeguarding the treatment by the use of the Roentgen rays. We attribute the good results and the lack of difficulty encountered in our treatment of these cases to our implicit following of the established technic as outlined by Hamman, and by the constant counterchecking and studying of the cases during the whole treatment by stereoscopic chest-plates.

In emphasizing therapeutic pneumothorax as a palliative measure we do not deny its value as a curative one, but we feel that we have not had sufficient time, experience or results to attribute to it this superlative value.

Exactly of what does this treatment consist in its present development, and what are the indications for its use?

---

* Read in the Section on Pharmacology and Therapeutics of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

Artificial pneumothorax is the introduction into the intrapleural space of an innocuous, slowly absorbable gas, which will collapse the diseased lung. The treatment is repeated until the clinical symptoms warrant the gradual cessation of the injections and the consequent normal reinflation of the lung.

This collapse and forced rest or immobilizing of the lung is indicated by the proved value of rest in the treatment of all tuberculous infections. Perhaps Nature, too, has given her suggestions as to palliative measures for tuberculosis, in the restricted muscular action of the chest, the pleuritic effusion, the hydropneumothorax and the closing of a large lesion with the drawn-over heart, often found in these cases.

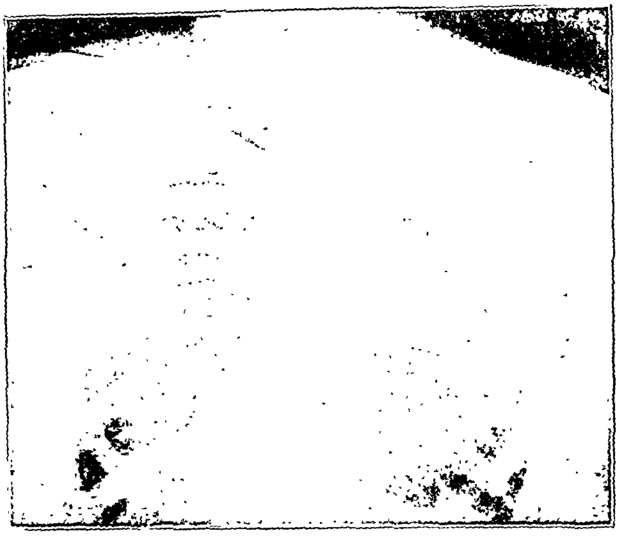

Fig. 1 (Case 1).—Before collapse.

The lack of contra-indications in properly selected cases is the best recommendation for induced pneumothorax. The operation is simple, the danger slight, the shock nil, and the effects most satisfactory.

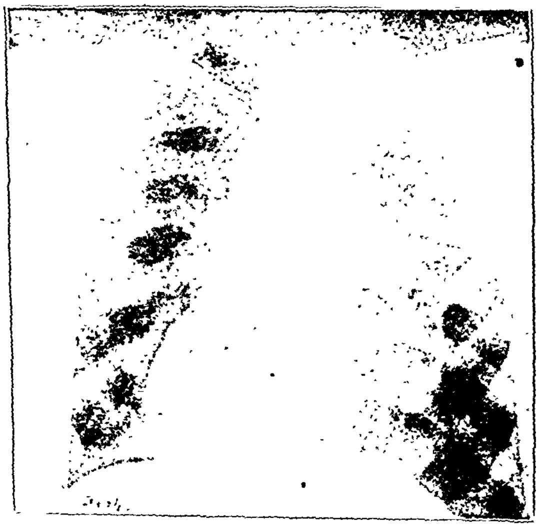

Fig. 2 (Case 1).—After collapse.

The results and effects of this therapy are positive. The principal pathologic findings after collapsing the lung are that the cavities are emptied in part or in whole according to the extent of the pleural adhesions, caseous areas have become cicatrized, and above all, an extensive overgrowth of the fibrous tissue is permitted during the enforced lung rest, which is Nature's best method of healing such a condition.

The clinical effects of pneumothorax are most encouraging, and are really what we have been working for, in the absence of definite proof that we might obtain a cure by this treatment.

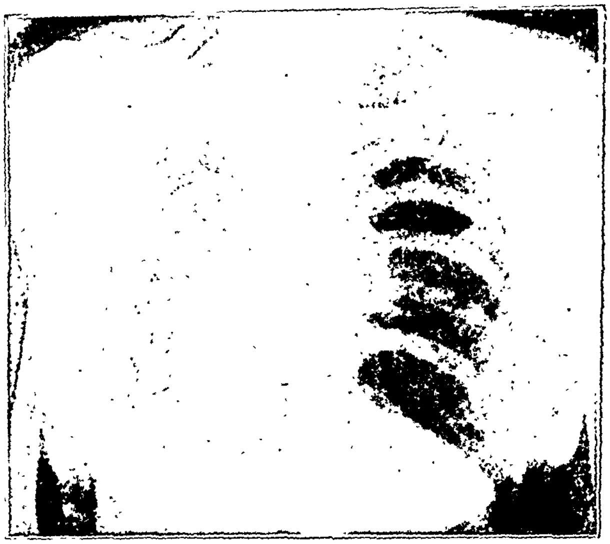

Fig. 3 (Case 2).—Before collapse.

In the first place, with the introduction of the nitrogen, the lung collapses, except where held out by pleural adhesions. Any pain which follows injection is always due to the stretching of these pleural adhesions. Pleural bands have invariably been made out in close proximity to an indicated area of tenderness. The pain is always sharpest just after refilling and gradually becomes duller. It is remarkable, but true, that a patient suffers no other pain and comparatively little inconvenience of any kind, even when a whole lung is collapsed to a mere solid mass lying close to the spinal column. With the progressive treatment, all detrimental symptoms abate. The diminished amount of retained infectious material shows the usual results of lessened toxic

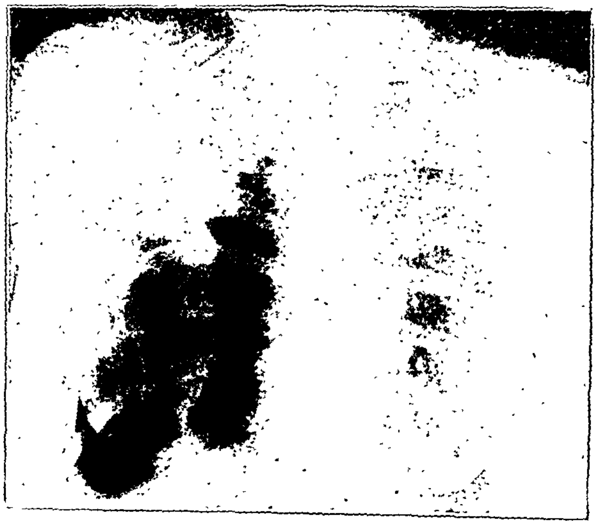

Fig. 4 (Case 2).—After collapse.

absorption—a fall in temperature and a reduced number of night-sweats, increased strength and appetite and final gain in weight. In addition, both the cough and the sputum are greatly lessened, and the elimination of the tubercle bacilli makes the patient less a source of infection; but the value of the treatment is best seen when a restless, despondent, hectic, emaciated, dependent cripple is transformed into a live, happy, resourceful being, who sleeps and eats well, and who goes about the grounds recommending the treatment to all who will listen.

These possibilities are facts. We have four such patients who have resumed work with our permission and two who have done so without it. It is a common thing for our patients to dress themselves after a filling and walk some distance to their wards; several even

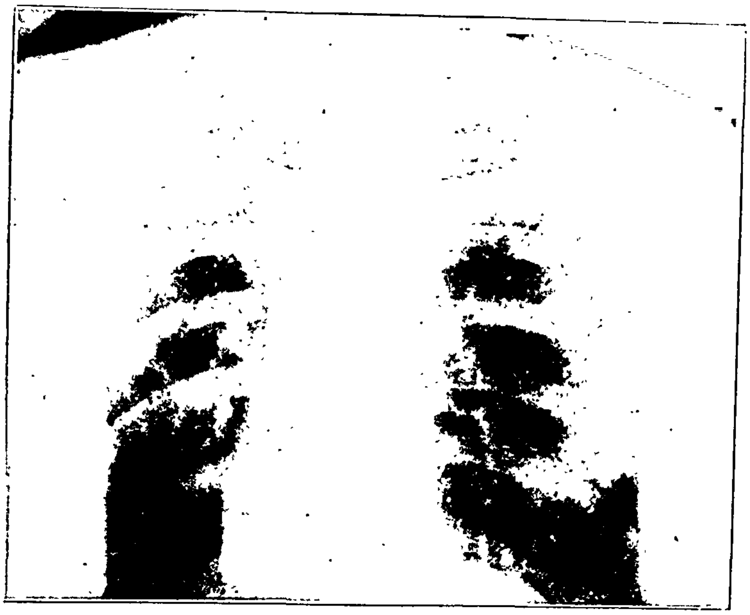

Fig. 5 (Case 7).—Before collapse.

Local anesthesia, perfected apparatus, accurate technic, careful asepsis, the ability of the one lung to collapse and of the other to carry the double burden, and the accessibility of the patient for the necessary refillings, form the most important items. The careful selection of cases (not very determinate as yet) often predestines success, and the Roentgen rays prove that refilling should be frequent and the gas-pressure slight, the amount of gas injected being just sufficient to keep the lung collapsed and no more. If the negative pressure is raised to zero we have found it to be more than enough.

We should like to dwell on each and every one of these essentials for success, but they and the dangers or complications encountered have been adequately written up so recently that we think it will be sufficient merely

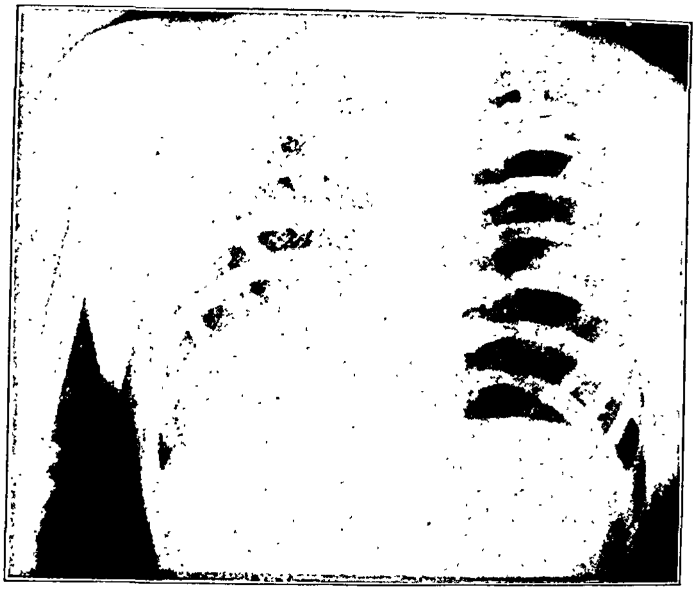

Fig. 7 (Case 12).—Before collapse.

First. Heart-misplacement and therefore derangement of blood-supply, a strain of the aorta, or a kink in the vessels resulting from too great pressure.

Second. Break in the mediastinum, from too great a pressure.

Third. Gas embolism, which might result from a puncture of the lung and the needle entering an artery. The possibility of this can never be entirely done away with, in using Forlanini's thoracentesis, but careful watching of the manometer and skilful manual technic will reduce this risk beyond the necessity of employing Brauer's thoracotomy, in our opinion.

The fourth danger is that of infection of the pleural cavity and resultant pleural effusion, and suggests a break in the asepsis. Effusion occurs in about one half of the generally reported cases.

The fifth, emphysema, is really more an inconvenience than a danger.

A sixth danger, abnormal conditions, has been avoided by never giving an injection during the menstrual period or just following a debauch.

From this consideration of the essentials for success and the hindrances to the success of artificial pneumothorax in the treatment of pulmonary tuberculosis, we can deduce this much: The treatment is certainly palliative, as a rule, and offers relief when usual methods of treatment have been unsuccessful. It is of especial value in the control of pulmonary hemorrhages. While it will possibly never become a routine treatment for consumption, its use will certainly be indicated for those with quiescent lesions on one side and acute recrudescence of the other, and for such advanced cases as may at least profit by the certain amelioration of clinical symptoms. Our opinion is that eventually it will be utilized for much earlier lesions, and the collapse will be obtained by more radical surgery, when the pleural cavity is obliterated by adhesions.

If we stop here, however, we have progressed very little farther than our predecessors. Our first point was to prove artificial pneumothorax a palliative measure; our real advance was to show how the constant use of the Roentgen ray in the treatment predetermined success and prevented disaster.

By the use of stereoscopic roentgenograms, we have been enabled to select cases, to watch the progress of the disease, to determine the extent of the lung collapse, to note the pressure on the heart and mediastinum, to exclude pleural effusion, and to safeguard the unfilled side.

From roentgenograms, as from physical examinations, we cannot ascertain whether we may or may not enter the pleural cavity. Of course the plates show us the fibrosis, and we know that when there is but a small amount of connective tissue entrance is usually easy, and when there is great fibrosis, entrance is difficult or impossible; but among the intermediate cases it is hard to differentiate.

The roentgenograms, however, do give us accurate information when percussion and auscultation fail; for we have learned from stereoscopic roentgenograms that it is almost impossible to map out accurately the extent of pneumothorax by percussion, because in some cases the lung is collapsed anteroposteriorly and in others from the mediastinum toward the chest wall; in others the lung is adherent to the chest wall as a streamer, collapse taking place around the various attachments, whereas complete collapse from chest wall to mediastinum is rather the exception. It is of great interest in any of these cases to watch the cavities becoming gradually *obliterated* by successive injections of the gas. The position of the heart cannot always be made out by percussion or auscultation either, as it is frequently pushed from the left posteriorly, rather than altogether from the left to the right. In short, these conditions can be accurately determined only by the Roentgen rays. Also, it is a great satisfaction to us to be able to say that in no case in which the gas has been injected has pleural effusion developed, and we are very glad to have our roentgenograms to substantiate our statement; but perhaps the greatest value of roentgenography here lies in being able to watch the progress of disease in the uncollapsed side.

We now present the report of twenty cases from the Cincinnati Tuberculosis Hospital in which we have given treatment with therapeutic pneumothorax as a palliative measure, safeguarded by the use of stereoroentgenograms.

Of the twenty cases treated six cases should not receive consideration as a palliative treatment for pulmonary tuberculosis. Two patients refused further treatment after the first injection, and in four cases we did not gain a satisfactory entrance into the pleural space, so that of the twenty cases treated we have fourteen which represent at its best therapeutic pneumothorax in pulmonary tuberculosis. The accompanying tabulated classification of the cases will present them perhaps more clearly.

CLASSIFICATION OF CASES

Condition before treatment:	
Unilateral	1
Bilateral	19
Hemorrhage cases	6
Cavities without hemorrhage	5
Cavities with hemorrhage	5
Condition during treatment:	
Failed to get in	4
Pleural successfully found	16
Filled but once	2
Results of treatment:	
Gained in weight	6
Losing in weight	6
Neither lost nor gained	2
Gained but now losing	3
Activity opposite side increased	1
Sputum reduced	14
Tubercle bacilli in sputum reduced	9
Sputum became negative	5
Cough reduced	14
Temperature reduced	10
Hemorrhages recurred after treatment	1

REPORTS OF CASES

CASE 1.—Motorman, aged 32 (Figs. 1 and 2). Bilateral lesion; right side most extensive. Has had numerous severe hemorrhages. Collapsed right side. Hemorrhages and cough controlled; fever normal; gained in weight. Had a relapse with hemorrhage during car strike, but has recovered. Is now doing well.

CASE 2.—Woman (Figs. 3 and 4) has bilateral lesion most marked on left side. Cavity in left upper. Has had several very severe hemorrhages. Left side collapsed. Cavity closed by pressure from mediastinum to lateral wall. No hemorrhage since first injection. Patient is doing well, but there is evidence that the disease is extending in right side.

CASE 7.—Man, aged 34 (Figs. 5 and 6). Bilateral, left most extensive. Many severe hemorrhages which have entirely ceased since first injection. Cavity is much reduced and patient is doing well.

CASE 12.—Woman, aged 18 (Figs. 7 and 8), had all symptoms of florid phthisis; temperature 104, etc. Examinations showed bilateral lesion with cavities in upper left. Left side completely collapsed, cavity emptied. Patient gained 12 pounds. Temperature normal. Sputum negative, cough reduced.

ABSTRACT OF DISCUSSION

DR. CHARLES L. MINOR, Asheville, N. C.: This subject is so vast in scope that I cannot possibly go into its details as I should like to do. The essentially important matter is the proper use of the manometer as a guide to the performance of the operation. Anybody working without such an instrument is criminally negligent, for air embolism may occur and may suddenly be fatal, whereas by the use of the manometer it should become almost impossible. When the needle has been introduced into the chest no one with any prudence will turn on the gas until he has first connected to the needle the manometer and seen whether or not there are negative fluctuations of air amplitude, usually at least 1 cm. If these are present, he can safely turn on the gas and allow it to flow. Further, the pressure of the gas in the chest should be tested on the manometer after each 100 c.c. have flowed in. In this way it is possible constantly to know the intrathoracic pressure and to avoid raising it too high. That this may be dangerous is proved by the fact that there is a case on record in which overpressure caused the gas to break through the mediastinum and produce a double pneumothorax. The safe pressure to use is something under 200 c.c. of water; I have gone as high as 170 or 180 c.c., but others have gone well above 200 c.c. without bad effect. Whatever the pressure indicated, if severe pain and marked shortness of breath occur, the operation should be temporarily stopped, but moderate pain is quite natural and can be disregarded. One of the great troubles of the operation is that, in some cases, the other lung wakes up into activity and causes the operation to be a failure. To avoid this, we should be careful to introduce the gas slowly, not over from 1 to 300 c.c. at the first operation, although Dr. Brauer uses as high as 1,800 c.c.; gradually increasing the amount of gas each time, we can introduce much larger quantities, but, as Dr. Durham has noted, it is not necessary to do more than keep up a moderate pressure in order to keep the bad lung collapsed. I do not, however, agree with him that the pressure should not be positive, but only neutral.

It is not a question of the number of cubic centimeters which you put in, but of the amount of pressure you produce. Reinjections should occur at first every two or three days, but finally at longer and longer intervals until they come every two or three months. As fibrous tissue forms, however, so much pressure is not needed to keep up collapse. The general rule is to keep the pressure up in the chest for from one to three years, when it is allowed slowly to reexpand. There is a tendency in this country to be too radical in the choice of cases, but, at present at least, this procedure should be confined to hopeless, advanced cases in which no other measure is applicable; patients who, in all probability, are going to die, but in whom the good lung is only moderately involved are excellent for the application of the procedure. The ideal indication is a destructive process *in one lung with the other lung in excellent shape.* Another indication is uncontrollable hemorrhage, which at times it stops with marvelous rapidity. The apparatus can be home-made for about nine dollars or bought from a dealer for forty dollars.

Dr. C. K. Roys, China: Have you used oxygen instead of nitrogen?

Dr. Kennon Dunham, Cincinnati: Oxygen is absorbed more rapidly than nitrogen. Some operators advise that oxygen be used to avoid air embolism on the principle that if it enters a vein and is carried into the circulation it will be absorbed quickly and no harm result. Air embolism is best avoided by an intelligent use of the manometer and reliance should not be placed on the character of the gas used. I purposely avoided describing the manometer and its readings because that has been so perfectly done by Hamman and Sloan. Two men should be associated in this work. When I am here Dr. Rockhill stays at home and sees that the patients are properly filled and vice versa.

I desire to emphasize the comparatively slight pressure necessary and the slight pressure advisable. When we go from a negative pressure to a neutral pressure we have usually gone far enough and *a slight positive pressure is all that is ever permissible.* I am sure that within a year Dr. Minor will be advocating this point of technic as strongly as we are. Much trouble has been unnecessarily caused by the great amount of gas injected and the high positive pressure obtained. With a patient lying comfortably *on the table* and the manometer recording perfectly, there is great temptation to inject a few hundred more cubic centimeters of gas. This may be just enough to cause undue pressure on the opposite side and to prevent the perfect recovery which should have been expected. Finally, the patients gain weight, eat better, sleep better, suffer less and more generally improve if attention is given to securing just the necessary amount of pressure and no more.

ETHER PERCENTAGES *

WALTER M. BOOTHBY, A.M., M.D.

BOSTON

Surgical anesthesia depends on the establishment in the blood and tissues of a definite ether tension, corresponding to about 15 per cent. of ether vapor in the alveolar air. My experience with the Connell anesthetometer, as well as the physiologic observations of Waller of London University, has demonstrated the fact that the "anesthetic tension" varies very little in different patients—the strong, robust alcoholic requires little, if any, greater ether tension than does a child for the same degree of anesthesia.

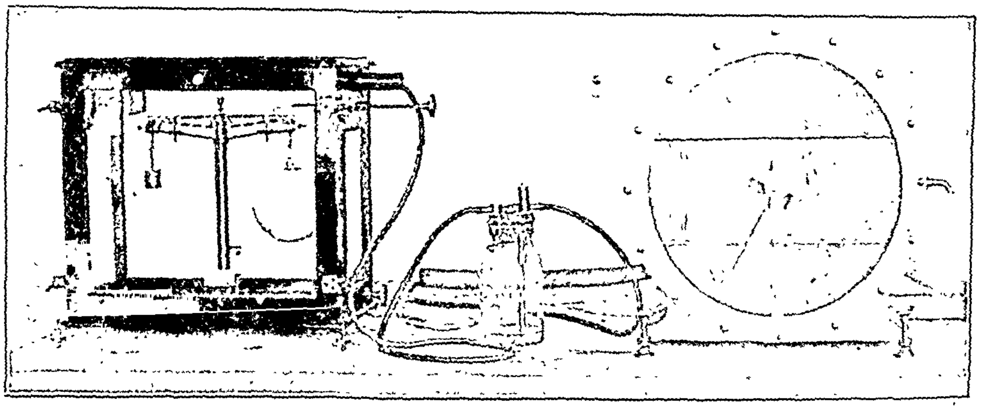

Fig. 1.—Apparatus for determining percentage of ether vapor obtained by passing air over liquid ether.

In order to induce anesthesia quickly, air containing approximately 30 per cent. of ether vapor should be administered for a period of from two to twelve minutes, depending on the size of the subject in relation to the rapidity of his circulation and respiration. By the early administration of strong ether vapor, diffusion occurs more rapidly from the inspired air, through the walls of the alveoli into the blood, allowing the latter in its turn to more quickly bring about in the tissues the tension of ether vapor requisite for surgical anesthesia. As the required tension is approached, the ether vapor in the inspired air is gradually reduced to 15 per cent. If less than 15 per cent. ether vapor is administered, outward diffusion occurs from the tissues and blood to the air and the anesthesia becomes lighter. On the contrary, the continuous administration of 15 per cent. ether vapor after the "anesthetic tension" is once established does not mean that the patient is receiving more ether, but merely that diffusion both in and out is prevented; in brief, a state of equilibrium is established, and so long as it is maintained a condition of safe ideal surgical anesthesia will exist.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

* From the Surgical Service and Respiration Laboratory of the Peter Bent Brigham Hospital.

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

Without question the anesthetomoter devised by Dr. Karl Connell of Roosevelt Hospital, New York, is the ideal apparatus to use. By it the "anesthetic tension" can be rapidly obtained and indefinitely maintained. Unfortunately this apparatus is not available to every one, and it seemed to me desirable that the ether percentages as obtained by the use of our more common forms of apparatus should be determined experimentally. This I have done, as well as to correct—in the light of our new knowledge—some of the erroneous beliefs which are so generally accepted in regard to ether anesthesia.

DESCRIPTION OF APPARATUS

Figure 1 represents the apparatus as set up for determining the percentage of ether vapor obtained by passing air over liquid ether contained in a Woulfe bottle and other "vapor" apparatus. On the left is the Waller gas balance calibrated to read off ether percentages from 1 to 50 direct.

In the center is represented the Richardson ether vapor apparatus; in the experiments, however, I used a 1-liter (1-quart) Woulfe bottle because the thermometer could be introduced into the liquid ether more conveniently by means of the middle opening; the bulb of the thermometer was always submerged.

On the right is shown a Bohr 10-liter gas-meter by which the volume of air per minute used during the experiment was obtained.

EXPERIMENTS AND EXPLANATION OF CHARTS

The air was passed through the meter, from the air-main in the laboratory, at a constant rate; taken over the surface of the ether and from there to the gas-balance. The temperature of the liquid ether and percentage of ether vapor were taken simultaneously.

In the chart (Fig. 2) the upper line represents the percentages, and the lower line the temperatures obtained when the air was run at from 4 to 6 liters per minute. The ordinate represents temperature and percentages; the abscissa time in minutes. While the ether is comparatively warm the percentage as recorded by the balance rapidly rises from 0 to 31 and then begins to fall slowly and parallel to the fall in temperature. If the percentage curve is extended backward as represented by the dotted line, it will be seen that at first the ether vapor was very strong—about 52 per cent.—corresponding to a temperature of the liquid ether of about 18 C. (64.4 F.).

Figure 3 is similar to Figure 2 in every respect, the more rapid rise and fall being due to the fact that the rate of flow of the air is twice as fast (10 liters per minute). The percentage curve extended backward by the dotted line gives 56 per cent. for a temperature in the liquid ether of 20 C. (68 F.).

Figure 4 represents an experiment in which the rate of air-flow was increased to 18 liters per minute. This rate corresponds pretty closely to that which an anesthetist would produce by his use of a foot-pump in a case in which the patient is difficult to etherize, for under such circumstances his tendency is to pump faster and faster. It is evident that such rapid pumping (and in deep breathers large volumes are necessary) defeats the very purpose for which it is done, because the large amount of air passing over the ether causes the latter to evaporate very quickly. As a result, the temperature of the liquid ether falls quickly far below 0 C. (32 F.), and therefore the amount of ether vapor in the air is less than 15 per cent. Concisely put, the faster the anesthetist pumps the lower will be the ether percentage obtained and the greater the difficulty, if not impossibility, of etherizing the patient. After the experiment had been continued for thirty-seven minutes the Woulfe bottle was placed in a water-bath at a temperature of from 35 to 37 C. (95 to 98.6 F.), with the result that the temperature of the liquid ether immediately rose and the percentage of ether vapor increased correspondingly. In the chart I have indicated by the heavy dotted line the percentage of ether necessary to induce and maintain anesthesia for the first hour in an operation for cerebellar tumor. The distance between the two curves, the upper representing the percentage needed and the lower the actual percentage obtained from passing air over liquid ether, illustrates forcibly the reason that an ordinary apparatus will often not anesthetize a patient. The advantage that can be obtained by immersing the ether bottle in warm water is as strikingly shown by the rise in the ether percentage.

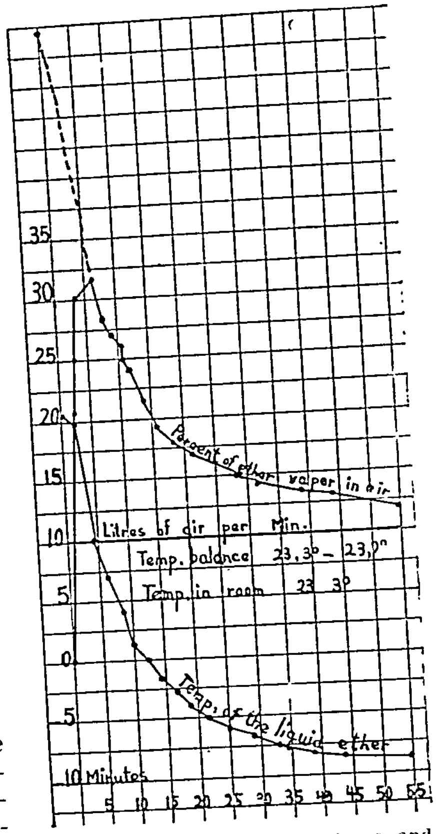

Fig. 3.—Chart of percentages and temperatures. Feb. 18, 1913. Same apparatus.

Furthermore, the fact that throughout the entire experiment the temperature in the balance varied less than 1 degree proves conclusively that any change produced by the warming device cannot be attributed in any way to a change in temperature of the inspired mixture of air and ether. This experiment confirms the earlier work of Cotton and Boothby[1] on the fallacy of warming the inspired air so far as affecting the patient by the temperature is concerned; the present work goes farther, however, and gives the true explanation of the practical value of immersing the bottle containing the ether in a bath of warm water.

Figure 5 illustrates the effect of immersing the ether bottle from the start in a water-bath at from 35 to 37 C. (95 to 98.6 F.), with the air flowing at 15 liters per minute. By this means we obtain much higher percentages, so high, in fact, that from the practical point of view, when a water-bath is used, care must be taken to dilute the mixture in some way before it is inspired by the patient.

---

[1] Cotton and Boothby: The Uselessness of Warming Anesthetic Vapors, Surg., Gynec. and Obst., 1912, xv, 724.

Figure 6 shows the percentage that would be obtained at a slower rate of air-flow. If a still slower rate was used a still higher percentage would be obtained for a longer time, because the liquid ether would not become so rapidly cooled by its quick evaporation. It must be remembered, however, that the patient may get two or three inspirations consisting of 50 per cent. ether unless care is taken to prevent this. Although no such great danger is present from the inhalation of strong ether vapor as there is of chloroform, yet it should be avoided. For this reason one must never use chloroform in this manner for the well-known reason that one single inspiration of concentrated chloroform may instantly and permanently stop the heart. I have frequently seen a chloroform bottle and ether bottle immersed in a water-bath in the same air-circuit, so that by the simple turning of a valve the air is made to pass over the chloroform instead of the ether; the purpose of this combination is to control patients difficult to anesthetize with ether.

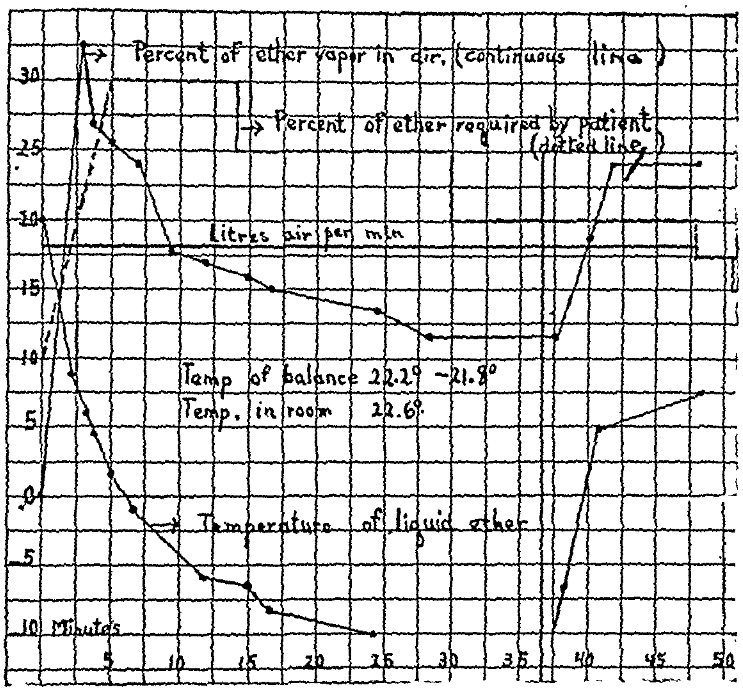

Fig. 4.—Chart of percentages and temperatures. Feb. 18, 1913. Same apparatus. At 37½ minutes the bottle of ether was immersed in water at 35 C. (95 F.).

No such difficulty should exist if an ether bottle of sufficient size (1-quart jar about half full) is used and immersed in water at 35 C. (95 F.). As the boiling-point of ether is 35 C. the water should never exceed this temperature. The water cools rapidly and must be kept up to 35 C. by constant addition of warm water by an attendant or by a small electric heater. Water at 35 C. will keep the liquid ether at a temperature of about 15 C. (60 F.) for the average rate of flow of air; at this temperature 45 per cent. ether vapor if undiluted with air can be obtained, a percentage far stronger than that which ever should be used without dilution.

In Figure 7 I have plotted the curve of the vapor tension of ether at different temperatures as determined by Regnault.[2] For comparison I have put in the points as determined by me in the preceding experiments. Many of my points fall directly on the true curve and most of the rest very close to it. The general close agreement between my experimental results and the true curve of the vapor tension of ether substantiates in a very satisfactory manner the fundamental correctness of my observations and deductions therefrom.

This curve can be made of practical use by placing a centigrade thermometer in the liquid ether of the vapor apparatus. At any given temperature of the ether one may be sure that one is obtaining the corresponding ether percentage; then if one has a valve which will accurately shunt the air-current so that one-fifth, one-fourth, one-third, etc., can be passed over the ether and the rest around the ether, a close approximation of the ether percentage which the patient is getting can be readily estimated.

NEW METHOD OF DETERMINING ETHER PERCENTAGES OBTAINED FROM A MASK

I shall now give a brief consideration to the ether percentages obtained from a mask. On account of the size of the dead-space of the balance, the readings taken will give only the average of a considerable number of respirations. Therefore the results obtained must only be considered as an average, since individual inspirations may be irregularly higher and lower.

For this problem I have arranged the apparatus shown in Figures 8 and 9. The artificial mouth and trachea of the patient consists of two brass tubes of ¾ inch diameter; one of these is used for "inspiration" and the other for "expiration." The tube for inspiration has a series of eight thermometers spaced at intervals of 2 inches, the first being directly at the mouth. The air is conducted back to the mask by the other brass tube containing water to saturate the air with moisture. This method affects the mask with warmth and moisture in the same manner as expired air, and yet does not influence the thermometers; therefore the temperatures as taken from the intake tubes will give a very fair indication of the temperature of air and ether as inspired by a real patient. The brass tubes or "artificial trachea" are immersed in a water-bath kept at a constant temperature of 37 C. (98.6 F., body temperature) by means of a small electric heater shown lying outside the bath. The mask used is placed on a little shelf that acts as a "face" and the mouth of the trachea opens directly under it. Ether is administered by a small constantly running stream, regulated to the desired amount by a stop-cock from the little glass container shown over the top of the hose; a glass tube, which can be easily moved, takes the ether to the mask and distributes it over the mask. The hand-pump was especially made for me, and by means of a check-nut can be set so that a single stroke will give any amount desired up to 1,500 c.c.; the number of strokes per minute and therefore the volume per minute are regulated as desired. The pump sucks in the air through the intake tube from the trachea and delivers it through the outlet tube to the balance; from the balance the air passes back through the second trachea to the mask.

In Table 1 are shown four of the many experiments by this method. During the stage of induction which requires 30 per cent. ether, the temperature of the inspired mixture falls to 12 C. (53.6 F.); as soon as anesthesia is induced, 19 per cent. ether is sufficient, and with this percentage the temperature rises to 23 C. (73.4 F.).* Still later, when only 15 per cent. ether is needed, the temperature would be even higher.

The well-known increase in depth of respirations in alcoholics appears to be due to the greater excitatory power of ether on the respiratory center in such subjects than exists in the case of non-alcoholics. The more expert the anesthetist the less excitatory effect does the ether have, and the easier it is to induce anesthesia. It is very hard for the beginner to increase the percentage of ether rapidly and yet smoothly without causing "suffocation" and therefore deep breathing on the part of the patient.

---

[2] Regnault: Chem. Kal., 1912, ii, 105, Table 77.

* Room temperature equals 24 C.

The difficulty of obtaining the high percentages requisite for the rapid induction of anesthesia in a deep breather is as great experimentally as it is in actual practice. The third experiment cited in Table 1 illustrates the tremendous amount of ether that must be poured on the mask to bring 24 liters of air per minute up to 30 per cent.

The words "on" and "off" after the percentages indicate the advantages to be obtained from a little anesthetic trick that deserves better recognition: namely, the greater ether percentage that can be obtained by placing the hands on the mask; the warmth of the hand aids the vaporization of the ether as well as preventing a leakage of air around the bottom of the mask. In practice I put a hand on one side of the mask and drop the ether on the exposed side, reversing sides about once a minute.

TABLE 2.—CALCULATION OF AMOUNT OF HEAT LOST BY RESPIRATION DURING ETHER ANESTHESIA

(Open wire mask with 16 layers gauze.)
Assumptions (based on experimental evidence):
Vol. of respired mixture (average): 10 L. per min., 600 L. per hour.
Containing: ether (average): 16 per cent., 96 L. per hour = ¾ lb (approximately).
Containing air (average): 84 per cent., 504 L. per hour.
Temperature of mixture as inhaled at mouth: 15 C.
Physical data:
Liter weight of ether: 3.53 gm. Specific heat of ether: 0.4796.
Liter weight of air: 1.29 gm. Specific heat of air: 0.2374.
Formula used:
Vol. × L. Wt. × Sp. Ht. × Deg. = Gm. calories lost.
Calculation.
Ether. 96 × 3.53 × 0.4796 × 22 = 3575 gm. cal. = 3.6 calories.
Air. 504 × 1.29 × 0.2374 × 22 = 3393 gm. cal. = 3.4 calories.
7.0 calories.

Careful consideration of all factors involved shows that there is practically no change from the average loss of heat by the vaporization of water from the lungs.

Vierordt gives the following average values of heat elimination:

	Daily Cal.	Hourly Cal.	Per Cent.
1. By urine and feces	47.50	1.98	1.8
2. By expired air: (*a*) warming air	84.50	3.52	3.5
(*b*) vaporization of water	182.12	7.59	7.2
3. By evaporation from the skin	364.12	15.18	14.5
4. By radiation and conduction from the skin	1,791.82	74.65	73.0
	2,470.82	102.92	100.0

These experiments explain away the apparent contradiction between the clinical fact that large, vigorous people, especially if alcoholic, need a great quantity of ether to produce anesthesia, and the physiologic law that all persons require the establishment in the body of approximately the same tension of ether vapor to produce the same depth of anesthesia. A recognition of this fact transfers the blame for a difficult and bad ether from the patient to the technic and ability of the anesthetist.

The question of the loss of heat directly attributable to the administration of the anesthetic mixture during an operation is one of importance. If there is an undue loss, effort should be made to prevent it; but if the loss proves to be comparatively small and therefore negligible, attention should be directed to more efficient and natural means of conserving the body heat.

The complete calculation is given in Table 2. It is evident that a loss of about 3½ calories per hour can be attributed directly to warming the ether, and an equal amount of bringing the temperature of the air itself up to body temperature. This makes a total of 7 calories; Vierordt assigns 4 calories as the normal amount.

It is more difficult to estimate the amount of heat eliminated through evaporation of water in the lungs. A consideration of the following facts leads to the conclusion, however, that little, if any, variation from the normal occurs. The points to be considered are:

Reference to Vierordt's figures at the bottom of the table will show that the normal elimination of heat by the lungs totals about 11 calories. During ether anesthesia it cannot at the outside be more than 16 or 17 calories, or an increase of 5 or 6 calories.

To contrast with these figures we must consider the amount of heat eliminated by the skin in the same period. Vierordt gives for this an average of 90 calories an hour. The danger to the patient of losing an undue amount of heat from the skin by evaporation, radiation and conduction is far greater than can take place from the lungs.

The conclusion seems inevitable that our attention should be directed to keeping the patient dry and warmly covered, and not to the procedure of warming the anesthetic mixture. Such warming of the inspired air is futile from the point of view of thereby sufficiently preventing a lowering of the body temperature during a surgical operation.

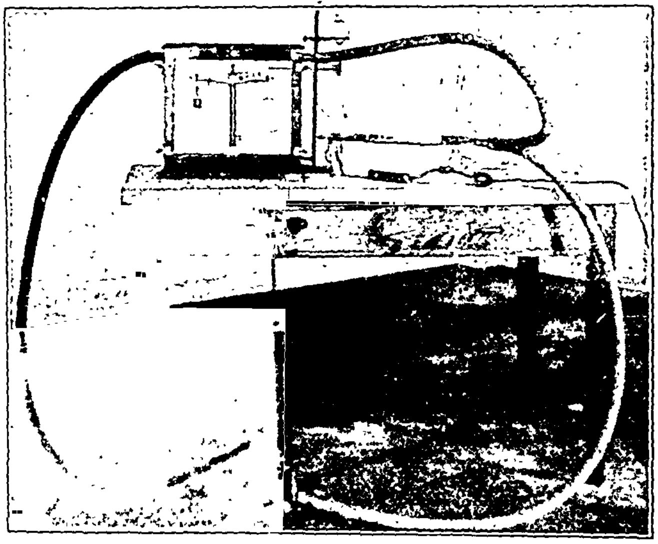

Fig. 3.—Apparatus for determining ether percentages from a mask, complete.

SUMMARY

I. 1. Apparatus and experimental details are given for determining the ether percentages that are obtained by passing air over liquid ether.

2. The advantage of keeping the liquid ether warm is demonstrated and the beneficial action of the procedure explained by showing the effect on the ether percentages obtained and the want of effect on the temperature of the inhaled mixture.

II. 1. A new method of determining the percentages of ether vapor and the temperature of the inspired mixture as obtained from a mask is described. The method used is considered to give results comparable to the percentages and temperatures existing in actual clinical etherization.

2. Clinically it is known that large, vigorous (alcoholic) patients require a great quantity of ether poured on the mask to produce anesthesia. Physiologically it is recognized that essentially the same tension of ether

vapor in the body produces in all subjects the same depth of anesthesia. It is pointed out that the clinically difficult cases are those in which the patients are deep breathers, those whose volume of air respired averages over 20 liters instead of below 10 liters per minute. The apparent discrepancy between clinical experience and the physiologic law, therefore, consists in the difficulty of the anesthetist in bringing such a large volume of air up to the percentage of ether required. In short, the anesthetist and not the patient is to blame for a difficult and bad ether.

III. From a calculation of the loss of heat directly attributable to warming anesthetic vapors, it is demonstrated that such loss is negligible in comparison to that from the body surface. Consequently it is futile to warm the anesthetic vapors.

508 Commonwealth Avenue.

ADMINISTRATION OF ALKALOIDS BEFORE ANESTHESIA *

ISABELLA C. HERB, M.D.
Instructor in Anesthetics, Rush Medical College; Anesthetist to the Presbyterian Hospital
CHICAGO

In the older records in medical literature there is abundance of evidence that many of the drugs which are employed to-day and which we are prone to consider recent discoveries were used by the ancients for the relief of pain during surgical and other procedures. They made decoctions from the leaves, bark and roots of plants and trees, which they drank, inhaled the fumes of or applied locally. In order to produce sufficient insensibility for operative measures very large doses had to be given. As a result patients frequently remained unconscious for hours or slept on to death. When the anesthetic properties of nitrous oxid, ether and chloroform were discovered, these agents rapidly replaced the drugs employed at that time, but it was generally thought necessary or expedient to reinforce them with drugs possessing hypnotic virtues. Morton, for example, gave large doses of opium before administering ether. As the action of anesthetic substances and the technic of their administration became better understood, the practice was quite generally abandoned. In 1900 Schmeiderin directed attention to the advantages of administering morphin and scopolamin alone or before inhalation anesthesia, and reported the results of this method in ten instances. The sedative and hypnotic effects of scopolamin on the insane is well known and Schmeiderin, an alienist, found that the insane could be more easily managed if given morphin and scopolamin prior to general anesthesia.

The administration of sedative drugs before anesthesia is of great importance and may be considererd from at least three points of view, namely, the patient's, the anesthetist's and the surgeon's. The three alkaloids most commonly employed are morphin, scopolamin and atropin. Before the physiologic action of scopolamin was well understood, Schmeiderin maintained that its action was antagonistic to that of morphin, and, unfortunately, his statements have been rather widely accepted. Hyoscin and scopolamin are now universally recognized by pharmacologists as identical chemically and physiologically. Therefore, the two names will be used interchangeably. Scopolamin and atropin are closely allied alkaloids belonging to the deadly nightshade family. The difference in the structural arrangement of the molecules composing them is believed to explain differences in their action. In order to facilitate a comparative study I have indicated in the accompanying table the actions of morphin, scopolamin and atropin in so far as they are concerned with the subject at hand.

That there are certain advantages in preliminary medication no one of experience will question, but the disadvantages must not be lost sight of. As the comparative safety of ether and chloroform has been settled through a clear understanding of their physiologic action, immediate and remote, so must the advantages and disadvantages of sequence, mixed anesthesias and preliminary medication be settled through a knowledge of the action of the drugs singly and in combination. It is well known that one drug frequently intensifies the action of another and this is especially true of those drugs whose actions are similar. The advantages said to accompany the administration of alkaloids before general anesthesia are as follows:

1. Less of the anesthetic is required. Glandular activity is diminished, thereby reducing the danger of pneumonia. There is less vomiting before and during anesthesia, therefore a smoother narcosis and also less postoperative vomiting.

2. The patient's apprehension of impending danger is lessened or altogether abolished and he enters the anesthetizing room in a quiet, sleepy manner. No resistance is made to preliminary preparation.

3. The stage of excitement is less pronounced and muscular relaxation is more quickly developed.

4. The patient remains asleep after completion of operation, hence suffers less pain. Let us analyze these advantages.

LESS OF THE ANESTHETIC IS REQUIRED

The lessened amount of the anesthetic required is not so important as is generally supposed. It has been conclusively shown experimentally that the degree of concentration of the vapor is of much greater importance than the length of the administration or the amount used. A very concentrated vapor used for a few minutes will do more damage to lung and kidney epithelium than a lesser concentration over a long period. The amount used is always relative. An experienced anesthetist uses much less than a novice. In considering the lessened amount of the anesthetic used the action of the substance which replaces it must be taken into account. That the danger from ether or chloroform is diminished has certainly not been proved. On the contrary, a study of the reports of deaths or other bad results clearly shows that the premedication was actually responsible either indirectly by intensifying the action of the anesthetic or directly through its continued action. There are always symptoms from ether and generally from chloroform which give adequate warning of approaching danger, and both are so evanescent in their action that the patient revives in a comparatively short time when they are discontinued; but, when enduring drugs or combinations of drugs have been previously administered, hours may elapse before the patient is past danger. A review of the literature shows that practically all of the reported deaths were caused by respiratory failure often accompanied by cyanosis and Cheyne-Stokes' respiration, suggesting a paralysis of the centers in the medulla. The conservative surgeon and anesthetist, although they may have seen no deaths or alarming respiratory depressions,

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

should not pass lightly over the experience of others, but should instead weigh seriously the advantages and disadvantages of a procedure which carries with it additional risk to the patient. Scientific men cannot fail to appreciate the reasonableness of maintaining a factor of safety by protecting the respiratory center and by exercising all possible care in the technic of anesthetization.

GLANDULAR ACTIVITY IS DIMINISHED, THEREBY REDUCING THE DANGER OF PNEUMONIA

Many of the postoperative pneumonias have nothing whatever to do with the anesthetic but are embolic in their origin and occur quite as frequently after local analgesia as after general anesthesia. A pneumonia which develops later than thirty-six hours after anesthesia should not be considered as due to the local action of the inhaled ether. Since the open method of etherization has become so universally employed, the tendency to postoperative pneumonia and nephritis has been materially lessened.

TABLE 1.—THE ACTION OF MORPHIN, SCOPOLAMIN AND ATROPIN

	Morphin*	$C_{17}H_{21}NO_4$, Scopolamin	$C_{17}H_{23}NO_3$, Atropin
Respiration	"Is a powerful [illegible] iratory center." [illegible] ffect is to lessen it [illegible] the rate and depth [illegible]	"Hyoscin is not in any dose a respiratory stimulant and in large doses it is actively depressant to this function."	"Moderate doses stimulate respiration, large doses depress it."
Circulation	"Exerts no direct action on the heart which continues to beat after respiration ceases." "Dilates the vessels of the skin leading to a flushing of the surface, especially the face."	"Small doses raise blood-pressure. Pulse is not ordinarily influenced."	"Increases blood-pressure and greatly accelerates pulse."
Nervous System	"Action is entirely central. Toxic doses produce paralysis of the respiratory center in the medulla."	"Generally depresses the brain producing sleep, but possesses little or no analgesic effects." "Occasionally produces restlessness with hallucinations and delirium."	"Large doses cause restlessness and excitement."
Pupils	"Contracted pupils."	"Dilates the pupil when administered internally or applied locally."	"Pupils dilate on internal administration or local application."
Glandular Activity	"Glandular secretion is less active unless nausea is produced when there is an increase of saliva and perspiration."	"Less glandular activity produces dryness of the mouth, throat and bronchi."	"Diminishes or completely arrests secretion."
Kidneys	"Depresses kidney function."	"Depresses kidney function."	"Depresses kidney function."

*Wood, H. C., Jr.: Pharmacology and Therapeutics, 1912. Stevens: Materia Medica and Therapeutics, 1909. Withaus and Becker: Medical Jurisprudence, Forensic Medicine and Toxicology, iv.

If the head is turned to the side as soon as the neck-muscles are sufficiently relaxed to allow it, and this can be done early in induction, the salivary secretion will escape at the angle of the mouth or remain in the cheek where it can be sponged out. This position has the further advantage of preventing the tongue from falling back in the pharynx and obstructing respiration. That the aspiration of mucus ever produces pneumonia is a doubtful possibility. If ether actually predisposes to pneumonia it does so by its direct action on the lung epithelium, and it is just as reasonable to presume that the checked secretion would render the unprotected cells more susceptible to irritation. Only rarely does the bronchial secretion become sufficient to interfere with blood oxygenation and when it does, the anesthetic may be withdrawn at a time when operative procedures will not be interrupted or interfered with; the mucus acting as a foreign substance will cause coughing when the patient is still asleep and the bronchi will be cleared by a few efforts. The anesthetic can then be continued. This seldom needs to be repeated. Because of the checked glandular secretions, patients frequently complain of great discomfort before and after anesthesia caused by the dryness of the mouth and throat at a time when water is denied them. Patients should be well protected during artificial sleep to prevent as far as possible loss of body heat. A similar statement applies during conveyance from operating-rooms through draughty halls and elevator shafts when resistance is low.

LESS VOMITING BEFORE AND DURING ANESTHESIA; THEREFORE A SMOOTHER NARCOSIS AND ALSO LESS POSTOPERATIVE VOMITING

There will be no vomiting during the induction of narcosis if the patient has been properly prepared. Vomiting during anesthesia always indicates a light uneven narcosis; in other words, with proper technic an absolutely smooth anesthesia is obtained without preliminary medication. The degree of narcosis must fit the operation and the character of the tissues being dealt with. The physician anesthetist, being familiar with the operative procedures, will anticipate the steps of the operation by keeping in touch with the operator and will produce a deeper narcosis when indicated. For example, after the clamps are placed in stomach and intestinal work only sufficient anesthetic is required to prevent vomiting, as there is little sensation in those structures. This is also true in thyroidectomies after the skin incision; little anesthetic is necessary until the skin sutures are being placed; then a deeper narcosis is essential lest the patient move and interfere with this step of the operation.

That postoperative nausea and emesis are lessened is questionable. That vomiting may be delayed is quite understandable from the continued action of the morphin and scopolamin. Patients feel nauseated or begin to vomit several hours after their return to bed or at a time when they should and probably would be over it if the nausea were due to the anesthetic.

APPREHENSION OF IMPENDING DANGER LESSENED

In lieu of the stupefying effects of morphin and scopolamin for producing a peaceful mental state we propose cheerful kindness, tactful sympathy, suggestions as to hoped for improvement or restoration to health, all of which will do much toward quieting a nervous patient. Excitement and haste should never be apparent; likewise, joking or other forms of hilarity in the anesthetizing room frequently impresses the nervous patient with fear that he is not receiving the close attention that the situation demands. A calm, courteous, masterful personality is a desirable requisite in an anesthetist as it does much toward inspiring confidence, and with confidence comes a sense of security and quiet. Final preparation of the field of operation during induction of narcosis not only shortens the anesthesia but helps to divert the patient's mind from the anesthetic.

STAGE OF EXCITEMENT LESS PRONOUNCED

When the technic of the induction stage is properly carried out the so-called "stage of excitement" is either absent or so slight as to be scarcely noticeable except in alcoholics. If patients of the latter class are arranged on the table with restraint straps so that they can be controlled, stimulation passes off in a few minutes. The development of muscular relaxation is only a matter of a little more time.

If an opiate is required for the relief of pain it can be administered when the patient is sufficiently awake to complain. Then one can be guided by conditions as to indications and contra-indications for its administration. Following nitrous oxid, it can be given at the completion of the operation while the patient is still on the operating-table.

Disadvantages of preliminary medication to general anesthesia may be summarized as follows: 1. Danger of respiratory paralysis. 2. Destruction of pupillary reaction. 3. Varying effects of the drugs. 4. Necessity of having a trained, experienced anesthetist in charge of the administration. 5. Predisposition to pneumonia in mouth, jaw and throat operations. Necessity for constant attendance until awake. After-effects as vomiting, headache and a blocking up of secretions. Prolonged respiratory depression which may favor pulmonary edema.

Let us now consider these disadvantages.

DANGER OF RESPIRATORY PARALYSIS

When machines are designed calculations are made to determine the points on which greatest stress will fall and an effort is made to strengthen or fortify these points, in order to provide for contingencies that may arise. In the case of anesthesia the respiratory center is the specially vulnerable point, and every hypnotic drug administered increases the burden which it is called on to bear; therefore, when we employ narcotic drugs before general anesthesia we display poorer judgment in our anesthetic technic than does the designer of machines. "Any dose of morphin that produces systemic effects depresses respiration. Hyoscin is not in any dose a respiratory stimulant and in large doses is actively depressant to this function" (Wood). The combined action of these two drugs is much greater than the sum of their separate action. In other words it is an example of the well-known therapeutic observation that one drug may intensify or augment the action of another, and this is especially true in a scopolamin, morphin, ether or chloroform combination. A much smaller quantity of chloroform or ether will paralyze the respiratory center if it is already depressed by morphin and scopolamin, and therein lies the danger.

Comparatively speaking, a patient may be fairly safe if an experienced anesthetist is in charge, but the method is especially dangerous if an untrained, inexperienced person is administering the anesthetic, as he may fail to recognize approaching respiratory failure and continue the anesthetic until breathing actually ceases. A review of the literature indicates that such respiratory failure frequently proves fatal, in spite of all efforts at resuscitation.

DESTRUCTION OF PUPILLARY REACTION

I unhesitatingly place next in importance to respiratory depression the destruction of the pupillary reaction. To one who is capable of interpreting properly this reflex, it is of the utmost value. There is nothing else which will denote so absolutely the degree of narcosis, or give more certain warning of approaching danger or indicate it more clearly when it is already present. Eyelid, pharyngeal and corneal reflexes when present simply denote a light anesthesia.[1] The amount of relaxation in the muscles of the neck and jaw, especially the latter, is of considerable value but not always reliable. A change in respiration and circulation occurs just before vomiting takes place and is so similar to the change when too deep a narcosis is present that without the aid of the pupil it is frequently difficult or impossible to tell which it is. The modus operandi called for being different in the two conditions, it is essential to be able to distinguish between them.

VARYING EFFECTS OF THE DRUGS

Because of the varying effects of scopolamin its purity was at first questioned but it is now well known that equal doses taken from the same specimen affect different people variously, or the same person is variously affected at different times. On account of such idiosyncrasies it has been suggested that patients be given trial doses on the day preceding the operation. It is also a wise precaution to inquire regarding the effect of morphin as not infrequently patients know of unusual reactions they are likely to exhibit toward this drug.

A TRAINED ANESTHETIST SHOULD BE IN CHARGE

It is often maintained that untrained persons should not administer anesthetics, to which I most heartily agree, but inasmuch as this is frequently done, the patient should be safeguarded in every possible way. The surgeon may be delayed a few minutes before muscular relaxation develops without preliminary medication, but it may be time or a life saved in the end. If respiratory failure develops when only ether or chloroform has been used, automatic respiration continues when once established, because the introduced poisons are quickly dissipated. But not so when drugs whose actions continue for some time, as morphin and scopolamin, have been administered.

PREDISPOSES TO PNEUMONIA IN OPERATIONS OF MOUTH, JAW AND THROAT

In operations of the mouth, jaw and throat an early awakening is most desirable. Morphin allays the reflex excitability of the air-passages, thus retarding coughing and favoring the retention of aspirated blood or vomitus in the trachea and bronchi, a condition which predisposes to pneumonia. Many people are unable to take morphin even in moderate doses without distress and vomiting and in such patients the disagreeable aftereffects of ether or chloroform would be aggravated. On account of the respiratory failure which may develop after the patient has been returned to bed, constant attendance is necessary for several hours. By checking sweating, it throws a greater strain on the kidneys whose function is already depressed. Allow me to cite from my own experience.

---

[1] The touching of the cornea is absolutely unpardonable and is as unscientific as it is unclean. Serious eye-infections frequently follow such uncalled-for practices.

A young woman was given 1/4 grain morphin and 1/150 grain scopolamin followed by a forty-five-minute ether anesthesia, during which time a laparotomy was performed for some pelvic trouble. The patient was returned to bed in fair condition. Nearly two hours later respiratory failure developed and she was revived by artificial respiration. About an hour later respiration again failed and artificial respiration was required a second time after which, although the respiration was shallow for a time, it regained its normal depth and frequency.

A similar experience was furnished by a robust man in middle life who was being operated on for fracture of the inferior maxilla.

The patient had been given 1/6 grain morphin and 1/100 grain atropin. The anesthetist was a trained, careful, observing man who assured me he had given a very small amount of ether. Respiration failed early in the operation and was with difficulty reestablished. The operation was continued and, when the patient complained, ether was given but respiration soon failed again. I was called from an adjoining room and we succeeded in establishing automatic respiration after some time and much anxiety. The operation was completed without further anesthetic. Although respiration was superficial and slow it did not cease again, but it was three hours before consciousness returned. There can be no possible doubt as to the cause of respiratory failure in either of these cases, for if it had been due to the ether, automatic breathing would have continued when *once* established by artificial means as there was no obstruction to the entry or exit of air.

Another experience, unfortunately, did not terminate so favorably.

A woman, aged 36, suffering with exophthalmic goiter was given 1/6 grain morphin. An hour later a light ether narcosis was produced and the right superior thyroid vessels ligated and the left vessels exposed ready for ligation, when respiration, which had been shallow, ceased. All effort at resuscitation proved futile.

It is true that the woman was an exceedingly "bad surgical risk" but I am satisfied that I have anesthetized many equally bad with no adverse results. There have been several other instances in my work in which alarming depressions or Cheyne-Stokes' respiration occurred without the development of paralysis which was probably due to an early withdrawal of the anesthetic. A familiarity with the literature shows me that my experience is in no way unique, as there are many reports, not only of temporary respiratory failures, but of deaths during narcosis and after patients have been returned to bed. Persons who were formerly enthusiastic supporters of the practice of administering alkaloids before general anesthesia have either abandoned it entirely or use it only in selected cases and give very small doses. Standing orders for the same fixed dose for every patient without regard for age, condition or operation are certainly not to be recommended.

The selection and administration of anesthetics should be placed on the same sound, scientific basis as asepsis or the practice of surgery. Competent anesthetists, like competent surgeons, are not agreed on all subjects, but we are coming to a better understanding of the physiology of anesthesia, and now that this very important branch of medicine is receiving a much-needed review, we may hope for better anesthetists and better anesthesias. I trust the time is not far distant when the study of anesthetics will be made an obligatory part of the curriculum of every medical college. Surgeons who work with regularly qualified anesthetists should consult with them regarding the selection of the anesthetic and the best method of administration, especially in the so-called "surgical risks." As the anesthetist is responsible for that part of the work, he should be allowed the privilege of giving or withholding alkaloids before anesthesia. The surgeon may be likened to the captain, the anesthetist to the pilot and the patient to the ship. The captain must of necessity depend on the pilot to steer the ship into and through the darkness of oblivion back to the light of consciousness. It is the pilot who, seeing the shoals and sandbars and realizing how near they are to disaster, questions the chosen course. The experienced pilot is much better able to cope with the situation than the inexperienced and yet he, too, although seeing danger ahead, may not be able to escape because the undercurrent, which is the method of anesthesia employed, is beyond his control.

INDICATIONS AND CONTRA-INDICATIONS

Indication: Local analgesia.

Contra-indications: Morphin and scopolamin are contra-indicated, in the case of patients in whom the respiratory center is depressed or likely to become depressed through operative procedures, obstructive dyspnea due to growth within or without the trachea causing pressure, or exophthalmic goiter; in operations about the mouth or throat; in the case of debilitated and cachectic persons or those suffering with continued sepsis; in patients presenting any degree of stupor or those susceptible to morphin, in children and elderly people, and when untrained, inexperienced anesthetists are administering the anesthetic.

CONCLUSIONS

1. The administration of morphin, scopolamin and atropin before general anesthesia has certain advantages but these advantages are not sufficient to counterbalance the risks attendant on their employment.
2. The loss of the pupillary reflex is a serious handicap, as nothing else indicates so unerringly the degree of narcosis.
3. That the danger from ether, chloroform or nitrous oxid is diminished is contrary to the evidence at hand.
4. They should not be employed when untrained, inexperienced anesthetists are in charge, as the anesthetic is rendered more complicated and extra skill and judgment are required.
5. The routine use of certain fixed doses before every anesthetic regardless of the patient's condition should be discouraged.
6. The employment of alkaloids has a distinct field of usefulness before local analgesia.

An Essential to the Success of Vaccine Treatment.—When the infection has been ascertained the question of a vaccine comes to the front. Vaccination is good when done under proper circumstances and preceded by a correct *clinical* diagnosis. Without a clinical diagnosis vaccination is mere scientific quackery. Good results are not likely to ensue when a pyosalpinx has been overlooked or an appendix full of pus.—*Clin. Jour.*

NITROUS OXID AND OXYGEN ANESTHESIA *

HARRY G. SLOAN, M.D.
CLEVELAND

Dr. Teter, Miss Hodgins and Miss Toot of Cleveland and Dr. McKesson of Toledo have administered nitrous oxid for surgical purposes over twenty thousand times without a death from anesthesia.

In the hands of the expert nitrous oxid is perhaps the safest known anesthetic, while it is perhaps the least safe in the hands of the inexpert. In equally expert hands ether may rival nitrous oxid as to immediate mortality, but ether is wholly outclassed by nitrous oxid as to the indirect postoperative morbidity and mortality. This striking difference is wholly beyond the control of the anesthetist because it rests on a chemical basis. The chemical reactions which favor nitrous oxid anesthesia and handicap ether anesthesia are the following: Nitrous oxid produces anesthesia by reason of its interference with the use of oxygen by the brain-cells; it apparently exerts no other influence except this oxygen interference; therefore its total effect on the body continues but a few minutes beyond the termination of its administration.

Ether, on the other hand, produces anesthesia by dissolving the lipoids of the brain; in addition, unfortunately, ether dissolves many other important lipoids in vitally important structures, such as the lecithin in the red corpuscles—it even breaks up this important structure, as is evidenced by the appearance of hemoglobin in urine, and by a postanesthetic anemia; ether also dissolves the specialized fats in the kidney, the liver and other organs, and, perhaps most unfortunate of all, the lipoids in the phagocytes. Hence it is that ether puts to sleep not only the patient but also the host of defenders, the phagocytes. The result of this is seen in the strikingly adverse effect sometimes following ether anesthesia in the presence of acute infections. These adverse ether effects are especially striking when compared with the effects of nitrous oxid.

Lung complications following nitrous oxid anesthesia are no more frequent than they are in normal persons who have received no anesthetic. I have never known a fatal postanesthetic pneumonia following nitrous oxid. Nitrous oxid plays a passive rôle so far as causing or increasing an existing nephritis is concerned, so that we no longer see postoperative suppression in elderly subjects following anesthesia. As a general anesthetic for diabetics, nitrous oxid is without question the anesthetic of choice. These patients apparently take it with no harmful results whatever, and up to the present I have neither seen nor heard of any deleterious effects following its administration for seventeen amputations in diabetic gangrene.

In comparing ether with nitrous-oxid anesthesia we may say that the dangers and difficulties of nitrous-oxid administration are technical and controllable, while those of ether are inherently chemical and uncontrollable. What, then, are the principal points in the technical control of nitrous oxid? First of all, the induction of anesthesia should be so gradual and careful that never for a moment is there cyanosis and never any muscular twitching on the way to complete unconsciousness. Nor is this all. After superficial unconsciousness is reached, the finesse is continued until regular rhythmic respirations are established and the stage of surgical anesthesia for nitrous oxid is reached.

This is not so deep as that for ether. The patient will "feel" the surgeon's instruments far more readily than under ether, which is a great advantage to the cautious surgeon as it warns him against needless roughness. Under certain circumstances nitrous oxid should be supplemented by ether, for instance, in the case of topers, patients under high nervous tension, and certain abdominal operations in which mass-traction in dislodging tumors must be made; under these or any other circumstances, pink nitrous-oxid anesthesia, if not adequate, is supplemented by ether. I am not an advocate of nitrous oxid alone, or of ether alone, but of good anesthesia.

Muscle tone is not so completely abolished as under chloroform or ether, because under nitrous oxid, surgical anesthesia is much nearer consciousness. Patients who go to the operating-room in fear show this much more markedly than do tranquil patients; in other words, the former are fighting subconsciously during the anesthesia. In order to overcome this factor by dulling their keener perceptions and rendering them oblivious to their surroundings, patients, excepting the very young, the old and the feeble, are given preliminary hypodermic injections of morphin and scopolamin from one and a half to two hours before being taken to the operating-room, so that by this means a large percentage of them retain no unpleasant memory of either going to or coming from the operating-room.

Muscle rigidity under nitrous oxid was formerly a handicap. Crile has now solved this problem so completely that, by following his method it is necessary to use abdominal tapes to hold the viscera out of the operative field in exceptional cases only.

The first factor in obtaining complete relaxation is to have the patient brought to the operating-room in a neutral state mentally, so far as any fear of the operative procedure is concerned. This is accomplished by the preliminary hypodermic. Then the muscular system lacks the tone that we see in preparation for a fight or flight with the accompanying fear. Having no mental anxiety, the patient falls to sleep under nitrous oxid as naturally as though at home in bed. Compare with their condition the state of the patient who is brought to the operating-room in mortal fear. Even when unconscious every muscle is tense, pupils are dilated, respiration is increased and labored, and pulse-rate accelerated. This state is prone to continue during the whole anesthesia.

The second factor in muscle rigidity is tissue-trauma during the operation. Every surgeon has seen muscles increase in tone and contract while they are being cut, and has noted how a lightly anesthetized patient strains while he is attempting to pack off the intestines. When the abdominal wall is being cut through the same reflex is involved as when one is expecting an abdominal blow and hardens his muscles as a protective measure. This persists, even while the patient is unconscious, as a reflex reaction to trauma. This factor is present under any general anesthetic up to that point at which muscle-tone is abolished by the depth of anesthesia. The factor of tissue-trauma may be disposed of by blocking the entire operative field with 1:400 novocain solution. The block, however, must be absolute, for if any impulses get through, the muscles at once increase in tone with the resulting rigidity. Technically this procedure demands considerable practice before the operator is able to open an abdomen and keep it flaccid like the open abdomen of a recent cadaver.

This practice of locally blocking the operative field is far-reaching in its influence. When one is manipulat-

ing an unblocked sensitive tissue, the immediate change in respiration and the restlessness of the lightly anesthetized patient teach him manual gentleness and precision, so that he comes ultimately to work as it were with "the velvet hand." This gentleness in turn permits the more kindly healing of wounds because there is less tissue-repair necessary. At the same time the patient's postoperative discomfort is lessened so much that the majority of patients are surprised at their ease and the shortened period of convalescence. Then in addition manual gentleness creates a feeling of sympathy between operator and anesthetist so that they come to play into each other's hands for the mutual benefit of the patient—the surgeon realizes that not a few anesthetic difficulties have their origin in the manipulations and so gives the anesthetist time to deepen the narcosis before completing his own procedure.

Only from one-half to two-thirds the usual amount of inhalation anesthetic is needed when the operation is done under complete anoci-association.

Nitrous oxid meets a need that no other form of narcosis meets: the patients who are most gravely ill take it best and are not in the least harmed by the procedure. Patients experience none of the disagreeable smothering sensation associated with the inhalation of ether vapor, but have merely the feeling of sailing away through the air and notice no disagreeable taste or smell, for the gas is nearly odorless. On regaining consciousness the patient has only one-third the nausea associated with ether, though occasionally there may be morphin nausea.

If we profit by Crile's suggestion in anesthetizing children, we are able to spare them a terrifying ordeal. The principle depends on a primitive instinct which prompts one to combat any condition which tends to curtail free respiratory exchange—in other words, to fight against asphyxia; so that if instead of placing a mask over a child's face one gives him the free end of the gas-tube to play with while the nitrous oxid is flowing, directing it in the meantime toward his nose, he will shortly become sleepy and doze off, when the mask may be applied without any protest.

There is less shock under nitrous oxid than under any other anesthetic. Shock cannot develop unless the nerve-cells have an ample supply of usable oxygen. In the production of shock, the latent energy of the central nervous system is changed to kinetic energy; that is, oxidation of the chromatin in the nerve cells is produced as a reaction to the incoming traumatic stimuli, and manifests itself in nerve impulses. Provided the stimuli from the periphery are sufficiently severe and long-continued, the central nervous system exhausts itself. Now the underlying principle of nitrous-oxid anesthesia is that it curtails the intracellular ability to use oxygen so that *a priori* one expects that shock would be much less marked under it than under any other which does not depend on this principle for its action. Crile and Prendergast have most ably demonstrated this fact in the laboratory and have shown that in animals traumatism under ether will produce twice as much shock as will traumatism under nitrous oxid. The same fact is seen clinically in our grave traumatic cases. In such, having in view the amelioration of the shock already present, nitrous oxid is the anesthetic of choice. Shock arising from our own operative procedure we never see, on account of the strict avoidance of the factors which are causative in its production.

The object of a surgical operation is not only to cure the disease but also to return the patient in the best physical condition and in the least time to his position in society, subjecting him in the meantime to the least possible danger. I think that nitrous-oxid anesthesia when used in connection with local blocking of the operative field, best furthers these aims. Technically this form of anesthesia is more difficult and exacting for the surgeon, yet I feel that we are amply repaid in sacrificing our convenience for the best interests of the patient because, first, our patients have returned to their work in progressively better condition; secondly, our mortality has progressively decreased so that in the last thousand cases in the surgical service at Lakeside Hospital in which anesthesia was given by the anoci method, there was a total mortality of only 0.8 per cent. In fact, the comfort of the patient at large has become such a marked feature of this method that the public with us is coming to demand this dual form of anesthetic.

INTRATRACHEAL INSUFFLATION ANESTHESIA (MELTZER-AUER)

REPORT OF A SERIES OF FOUR HUNDRED AND TWELVE CASES [*]

CHARLES H. PECK, M.D.
Surgeon to Roosevelt Hospital
NEW YORK

Meltzer and Auer have shown that continuous insufflation or air into the trachea under moderate pressure is capable of ventilating the pulmonary alveoli, of effecting the necessary exchange of oxygen and carbon dioxid and sustaining life for many hours when all respiratory movements have been abolished by curare.

They have shown that it is the most effective and ideal method of artificial respiration known. It then occurred to them that it might be a means of introducing ether vapor into the respiratory tract, and the extensive and careful series of experiments by which they developed the method of intratracheal insufflation anesthesia are too recent and well known to require review in detail.

This paper will deal simply with personal experience with the method on my service at the Roosevelt Hospital during the past two years in a series of 412 cases, including a great variety of conditions, in many of which we believe it to possess special advantages.

The cases of the series were distributed as follows:

Locations of Operations	No.
Head and neck exclusive of goiter...	77
Goiter and exophthalmic goiter.....	21
Thorax	17
Breast	25
Abdomen	137
Kidney and ureter................	25
Miscellaneous	110
Total	412

There have been no deaths or serious accidents in our series. When the tube is once in the trachea one has ready for instant use the most perfect means now known for the artificial respiration; consequently we have used it by preference in our most difficult and critical cases. We do not use the method to the exclusion of other forms of general anesthesia by any means. Gas and ether, gas and oxygen, drop ether, combined local and general anesthesia and pharyngeal insufflation are employed freely, the attempt being made to fit the anesthetic to the patient and not the reverse, but we do find many conditions in which we believe the intratracheal method to have distinct advantages. During the period in question 2,155 operations have been performed on the second surgical division, less than 20 per cent. of the total under intratracheal anesthesia.

---

[*] Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

Difficulty of intubation is and probably will continue to be the chief obstacle to a more general use of the intratracheal method. The difficulty, however, has been greatly exaggerated; all of our interns acquire the knack very readily and have trouble in only a small percentage of the cases.

In some cases the difficulty is real, for example, in obese patients with short and thick necks, or in those who do not relax readily under the preliminary anesthesia, for good relaxation is essential to easy intubation.

Sometimes the anesthetist will fail after several attempts, the tube entering the esophagus each time, causing irritating delay and prolongation of the preliminary anesthesia. When this occurs after two or three attempts it is our custom to have another man try, and often, although no more skilful, he will succeed at once as the first man, having once lost the way, is apt to repeat his mistake.

We have tried the Boothby-Cotton curved guide and other devices for intubating by the sense of touch, but prefer and use almost exclusively the Jackson direct-vision laryngoscope.

The anesthesia is essentially light, and in a few alcoholics and robust adults we have had difficulty in securing quiet anesthesia and good relaxation. The use of a preliminary hypodermic of morphin and atropin in such cases generally obviates this trouble, and in no instance during the past year have we had to abandon the method on this account.

SAFETY OF THE METHOD

With a suitable apparatus (many such have been devised, some simple, some very elaborate) we believe that the method is absolutely safe if certain cardinal principles of technic are understood and carefully observed:

1. Intubation should be done by direct vision, or, if by touch, with the utmost care to avoid trauma to the larynx or trachea.

2. The tube must not be too large, its diameter not more than half that of the glottis; 24 F. should be the maximum for the average adult, ranging down to 18 F. or even smaller according to the size of the larynx and of the patient.

3. The tube must not be inserted farther than 26 cm. from the incisor teeth; that is, its tip should be at least from 1 to 2 inches above the bifurcation of the trachea. A tube pushed on down into a bronchus and plugging it might cause serious mischief.

4. Overpressure must be carefully guarded against, best by a suitable safety-valve attached to the apparatus. The average pressure used is from 18 to 25 mm. of mercury; from 35 to 40 mm. is a safe maximum. If from a defect in the apparatus or from any reason the pressure is not known and under absolute control, the insufflation should be discontinued at once.

5. If the tube enters the esophagus by mistake, it should be disconnected and pressure made on the epigastrium to deflate the stomach before it is withdrawn and replaced in the trachea. We have had this happen a number of times, but have never seen any untoward results.

6. The ether vapor should be of moderate concentration, and must be absolutely free from droplets or spray of liquid ether. The apparatus devised by Dr. Karl Connell, assistant surgeon to the Roosevelt Hospital, has enabled us to make accurate observations as to the strength of ether required. The maximum strength used for maintaining anesthesia is 21 per cent. by weight, and this is graded down to about 14 per cent. as the operation proceeds. We have had no experience with higher degrees of concentration, but would fear possible pulmonary irritation.

SHOCK

We are convinced that shock is noticeably less with insufflation than with other methods of etherization, and believe that it is largely due to the complete relief of respiratory strain and the abundance of air continually present and rapidly renewed in the pulmonary alveoli. Dr. Meltzer has aptly referred to it as a luxury of respiration. The even delivery of well-diluted ether vapor and the accurate control of its strength is probably also a factor. The coincident relief of strain on the circulation is especially striking in operations for exophthalmic goiter and in severe and prolonged operations of various kinds, especially in anemic or debilitated patients.

Since we have used insufflation anesthesia in our most serious cases, we have rarely needed the intravenous saline infusions which we use during or at the termination of the operation, if the pulse shows signs of weakness or there is a marked fall in blood-pressure. This is not because we have lost faith in the saline, nor yet because the type of cases has changed; but I believe that fewer cases show evidence of shock since insufflation has been used in just the class of cases that formerly called for stimulation.

The relief of strain on respiration and circulation necessarily means a similar effect on the central nervous system, and this is shown in the absence of postoperative depression and the rapid recovery from the effects of the anesthetic and the operation.

PNEUMONIA

Experimental and clinical evidence has shown conclusively that neither pneumonia nor bronchial irritation is caused by insufflation anesthesia. Our experience coincides with this view, for while there have been in our series six cases of postoperative pulmonary complications, three only could be considered as possible ether pneumonias, and in none of these do we believe that the insufflation was responsible *per se*. It will bear repetition in relation to this point that the cases of this series have included the most difficult and serious of a busy service in the heart of a great city, on which is thrown a large number of desperately ill patients.

As this question is of vital importance in judging the method, brief notes of these cases are given.

We believe that insufflation not only does not cause bronchial irritation or pneumonia, but that it acts as a preventive, first, in bad breathers who are more or less insufficiently oxygenated and under respiratory strain, and who are continually aspirating mucus and saliva, and, secondly, in operations about the mouth and pharynx, by preventing aspiration of blood and detritus. This is of the greatest benefit in excisions of the tongue or jaw and various operations of the mouth, nose and pharynx. Such operations are greatly simplified by the use of the method, and the necessity of ever having to resort to a preliminary tracheotomy is practically eliminated. In this respect pharyngeal insufflation cannot take the place of the intratracheal method.

Of the six cases of pulmonary complications, two have already been reported.[1]

The other four cases are briefly as follows:

CASE 1.—M. G., man aged 45 years, was operated on Oct. 12, 1912, for acute septic cholecystitis with extensive localized peritonitis and perihepatitis. Cholecystostomy was performed with prolonged drainage of gall-bladder and suppuration of wound. The abdominal wound broke open on the twelfth day. Right lower lobe pneumonia developed on the second day, signs persisting about five days. The patient recovered. While the pneumonia was in all probability a complication of the disease and not due to the anesthesia, ether pneumonia cannot be excluded.

CASE 2.—J. A., woman aged 25 years, Syrian, operated on Nov. 15, 1912, for tuberculosis of rib and thoracic wall, was emaciated and showed signs of pulmonary tuberculosis. Right lower lobe pneumonia developed twenty-four hours after operation; later the upper lobe was involved; there were defervescence and recovery after a sharp course of eight days. This was a case in which the administration of ether in any form was an error; the pneumonia was as likely due to the preliminary anesthesia as to the insufflation.

CASE 3.—G. B., man aged 64 years, was operated on Dec. 7, 1912, for extensive indurated mass in pyloric region of stomach, probably carcinomatous and ulcerated. A palliative gastro-enterostomy was done. There were signs of consolidation in the right lower lobe, first detected six days after operation. Death occurred from pulmonary abscess with surrounding zone of consolidation twenty days after operation. This case requires no comment as it was evidently a complication of the disease and not due to the anesthesia.

CASE 4.—P. G., man aged 35 years, was operated on Jan. 16, 1913, for obscure abdominal symptoms. A malformation of liver (diminutive right lobe), great hypertrophy of omentum, and chronic appendicitis were found; there was a good deal of manipulation in the region of the liver during exploration. The preliminary anesthesia in this case was unduly long and deep, lasting thirty minutes. The intubation was accomplished only after repeated trials; the anesthetist was a beginner. Right lower lobe pneumonia developed promptly, subsided after five days and the patient made a good recovery. The preliminary anesthesia in this instance was unquestionably responsible for the pneumonia.

We have had no laryngitis or loss of phonation; when it occurs it is probably due to the use of too large a tube or to trauma in intubating.

Sore throat with pain on swallowing lasting a few days has occurred in a number of cases, due always to direct trauma to the pharynx in intubating.

Vomiting is less than in ordinary etherization, and seems to depend largely on the length and degree of preliminary anesthesia required to produce sufficient relaxation for intubation, or on the nature of the illness itself.

In 141 insufflations observed since January 1 by our present intern anesthetist, Dr. White, thirty-two patients vomited once (22.7 per cent.), twenty-four vomited twice (17 per cent.), and six vomited several times (4.2 per cent.), a total of sixty-two (43.9 per cent.).

For positive pressure in thoracic operations it is fast supplanting other more cumbersome methods, as, in addition to the facility with which the degree of pressure can be controlled, the automatic ventilation of the lungs is of the greatest advantage. The far-reaching influence which intratracheal insufflation will have on the development of thoracic surgery in the near future is scarcely appreciated as yet. Heart and great vessels, lungs, bronchi and intrathoracic esophagus, are accessible and approached with increasing safety.

CONCLUSIONS

1. Intratracheal insufflation, administered with accurate control of the strength and amount of ether vapor, is a new principle in anesthesia which in certain classes of cases has many advantages over other methods.

2. The difficulty of intubating and the necessity of inducing full surgical anesthesia before this can be accomplished makes this a method unsuitable for many short, simple operations. Its use should be restricted to the cases in which it has special advantages.

3. It is absolutely safe both as to administration and freedom from deleterious after-effects if a proper apparatus is used and the simple precautions mentioned in detail are observed.

4. It is an ideal method of differential pressure for operations involving the opening of one or both pleural cavities, greatly reducing the danger of intrathoracic operations.

5. It greatly lessens operative shock: (*a*) through the absolute relief of strain on the respiratory apparatus and coincident freedom from strain on the circulatory apparatus and the central nervous system, and (*b*) from the even, advantageous degree of anesthesia maintained. This is especially evident in aged patients, in those cachectic from malignant disease or anemia and debilitated from other causes. The disparagement of ether as an anesthetic as compared to nitrous oxid, so popular of late among the advocates of the latter, is based on observations of faulty methods of ether administration rather than the inherent toxic effect of the drug itself. The wide margin of safety with ether has so long permitted abuse with this drug that faulty technic has been assumed by its opponents as customary in its administration.

6. It prevents aspiration of mucus or saliva, vomitus, blood or other foreign matter into the trachea, simplifying and decreasing the danger of operations on the tongue, jaws, mouth, nose or pharynx, preventing aspiration pneumonia, and practically eliminating the necessity of preliminary tracheotomy in such cases.

7. It is especially useful in operations about the head and neck. The anesthetist is out of the way; the operative field is easily kept sterile and obstruction of the upper air-passages is absolutely prevented. The same may be said of operations on the kidney, the spine and in awkward positions in general.

8. The degree of anesthesia is under perfect control. Overetherization is impossible at or below 21 per cent. by weight of ether vapor. Insufflation of pure air for the last few moments of the operation hastens the recovery of consciousness and minimizes the after-effects.

30 West Fiftieth Street.

Fly-Borne Typhoid.—C. E. Terry in the *U. S. Public Health Reports*, gives an account of the control of typhoid in Jacksonville, Fla., showing a marked reduction in the typhoid rate since the enforcement of rules requiring the fly-proofing of privies, the screening of sick-rooms in cases of typhoid, and the destruction of flies by poison or sticky fly-paper. He believes that the fly transmits infection through its excreta rather than by means of the specific bacilli carried on its feet from infectious material; also, that the fly bred in infectious material is a carrier for a longer period and hence more dangerous than the insect obtaining its infection through contact or feeding after maturity.

LOCAL ANESTHESIA *

JAMES F. MITCHELL, M.D.
WASHINGTON, D. C.

In 1907 at the meeting of the American Medical Association at Atlantic City, I presented a paper on local anesthesia and in the following year a report through the anesthesia commission on the extent to which it was used in this country. Since that time there have been important developments; the field has been broadened and the popularity of the method has increased both at home and abroad. It has seemed that a general review of this development might be of interest.

Probably the one greatest factor has been the introduction of novocain as a substitute for cocain. First clinically tested by Heinrich Braun in 1905 and extolled by him in several papers,[1] it has been generally adopted and is now recognized as the best and safest substance for the production of local anesthesia. It has the great advantage of being about seven times less toxic than cocain, and its solutions stand boiling. It is conveniently supplied in tablet form in combination with synthetic suprarenin. In preparing solutions these tablets are dissolved in 0.6 per cent. salt solution to which is added a little hydrochloric acid. For infiltration purposes 0.25 to 0.5 per cent. solutions are used and as much as 125 c.c. of the latter strength may be injected with perfect safety. Braun states that he has repeatedly used as much as 250 c.c. (1.25 gms.) of this strength and has never seen trouble therefrom, but cautions that we should in spite of this ever bear in mind that novocain is a poison. We can therefore infiltrate very extensively with no fear of toxic effect, a fact which accounts in large part for the extension of local methods into new fields.

Anesthesia is probably obtained somewhat more quickly with cocain and where small amounts only are necessary I still use it; but, for all larger infiltrations, novocain is the choice.

Urea and quinin hydrochlorid, suggested by Thibault and popularized by Hertzler[2] and others, is another anesthetizing agent which has proved of value. It has in its favor practically negative toxicity, its control of postoperative bleeding and the fact that anesthesia obtained by it may last for several hours or days, thus eliminating postoperative pain. It is thus well fitted for rectal work and is said to be especially useful in the removal of tonsils. The ordinary strength of the infiltration solution is from 0.5 to 1 per cent. Anesthesia is obtained slowly and one should wait at least fifteen or twenty minutes after the injection before beginning an operation.

In 1908 Bier[3] presented an entirely new method of obtaining anesthesia of the limbs through the medium of intravenous injection of novocain. The limb is rendered perfectly ischemic by the application of a rubber bandage from the periphery to a little above the point at which a vein is to be exposed. At the central edge of this expulsion bandage an Esmarch tourniquet is tightly placed over a broad surface. The expulsion bandage is removed and a handbreadth or so below the first tourniquet a second is applied. Between these two a vein is exposed, usually the internal saphenous in the leg and the cephalic, median or basilic in the arm. The vein is ligated centrally and a cannula introduced distally and tied in place. Novocain (0.5 per cent.) is then forced into the vein under considerable pressure—from 60 to 100 c.c. in the leg, 40 to 70 c.c. in the arm—the cannula is removed and the vein tied. In one or two minutes there is complete anesthesia in the area between the tourniquets—direct anesthesia—and in ten or fifteen minutes in the parts distal to the second tourniquet—indirect anesthesia. There is also complete motor paralysis; so that there is obtained as thorough relaxation as under general narcosis, rendering this method applicable for any operative procedure. The anesthesia persists as long as the central tourniquet is left in place and disappears quickly after its removal. Bier's longest operation lasted one and three-quarter hours. Hayward[4] in November, 1912, reports from Bier's clinic 375 operations under vein anesthesia; including amputations, joint resections, fixation of fractures, tendon transplantations, removal of varicose veins, etc. There was complete anesthesia in 93 per cent. and in only 3 per cent. was narcosis necessary. There were no accidents or bad results. Kaerger[5] from the same clinic reports 150 further cases and gives the details of the method as applied to minor operations on the hand and foot, a most useful procedure in office or dispensary work.

Undoubtedly venous anesthesia furnishes us a useful addition to our means of carrying out operations in non-septic conditions of the extremities, but the discomfort of the tourniquet is often a factor which must be considered.

Goyanes[6] in 1909 suggested a similar procedure except that he injected the anesthetic by means of a fine needle directly into an exposed artery. Ransohoff[7] in 1909-10 used a similar method, but did not exsanguinate before injecting. The intra-arterial method seems to show no advantages over the venous and has the disadvantage that arteries are more difficult of access than superficial veins.

A knowledge of sensory nerve-distribution renders easy the anesthetization of distal portions of an arm or leg by perineural or endoneural injection. Crile[8] in 1902 injected the several cords of the brachial plexus after exposing them. Hirschel[9] first obtained anesthesia of the whole arm by injecting the plexus in the axilla without incising the skin and Kulenkampff,[10] stimulated by his paper, has worked out a method by which he reaches the plexus above the clavicle. He gives anatomic details and reports twenty-five cases, in fifteen of which total anesthesia was obtained and in only three of which a little ether was needed.

For the leg Läwen[11] in 1911 presented the technic of reaching through skin punctures the various nerves so as to anesthetize the whole limb and in 1912 Keppler[12] published an extensive article with further details and

reports of cases. Babitzki[13] quite recently described a method whereby the sciatic nerve can be reached at the foramen for direct endoneural injection, the needle being introduced through the gluteal muscles and controlled by a finger in the rectum.

Franke and Posner[14] contribute from the Heidelberg clinic in 1912 a study of the sensory nerves of the pelvis and perineum with the technic of reaching them by puncture. They report several perineal prostatectomies and in a footnote ten additional ones, all completed under absolute anesthesia.

Ruge[15] cites numerous vaginal operations and two complete vaginal hysterectomies accomplished painlessly under simple infiltration with novocain, and from Knight Smith[16] comes a report of two successful and painless cesarean sections by the same method. Läwen's method of paravertebral nerve-blocking, reaching the nerves at the spinous processes of the vertebrae, was applied by Finsterer[17] to abdominal work. He obtained perfect anesthesia in four out of six cases and recommends this procedure especially for removal of the appendix. Kappis,[18] applying the same method, has removed the kidney in three cases; Schumacher[19] recites thirty-five thoracoplasties and Heidenhain[20] four laminectomies. Kappis found that absolute anesthesia could thus be obtained for operations on the gall-bladder and stomach. This is of particular interest in showing that the vagus is not concerned with the sensory innervation of this region.

The head has been a special field of investigation. In the papers of Braun, Offerhaus[21] and Härtel,[22] not only are the methods of reaching the individual branches of the fifth nerve accurately mapped out; but even the injection of the gasserian ganglion itself is detailed with mathematical accuracy. All operations in the field of supply of the fifth nerve are done by preference under local anesthesia by these surgeons. Braun states that local anesthesia has made of resection of the upper jaw quite another operation, which may still have its horrors and its difficulties but has quite lost its danger; that patients come through it with absolutely no collapse and quite as fresh as before it began and scarcely need to go to bed. Of ten patients he has lost none and had no pulmonary complications. Härtel reports nine cases in equally glowing terms.

Excision of the tongue or lower jaw comes under the same category. Härtel's brilliant article,[23] published in December, 1912, details the anatomic approach to the gasserian ganglion by needle puncture and its reading would well repay any one interested either in the subject under discussion or the injection treatment of tic douloureux. The ganglion is reached through the foramen ovale and injected with 1 c.c. of 2 per cent. novocain-suprarenin solution. Anesthesia is obtained almost immediately and lasts about an hour and a half. Härtel reports sixteen operations in which he has used this method, in nine of which the ganglion was injected on both sides. The operations included six resections of the upper jaw, three of the lower jaw and two of the tongue. Besides these there were fourteen patients in whom the ganglion was injected with alcohol. In all there were thirty-nine attempts at puncture of the ganglion, of which he reports twenty-eight as easy, seven difficult and four with no anesthesia obtained, so that the ganglion was probably not reached.

The neck had long been a favorite situation for work under local anesthesia and the accomplishments of Bier, Kocher and others are well known. The progress in this field in the last few years is along old lines, but the possibilities have been greatly increased by the introduction of novocain because of the enormous amount of the solution which can be used. Braun reports, that from 1908 to 1911, his 150 thyroidectomies have without exception been done under local anesthesia.

To one accustomed to the use of cocain administered as sparingly as possible, it is surprising how simple and painless these operations become with the generous novocain infiltration as recommended by Braun. The third edition of his book on local anesthesia, just published in the last few weeks, is a storehouse of interesting and wonderful descriptions of the conquest of sensation in all parts of the body. The technic of the injections for various operative procedures is given in detail, illustrated by charts and photographs in such a way as to make a practical working guide.

The work of Crile on shock and anesthesia has been of great value. Showing that shock has as its basis a definite injury to nerve cells, he has sought to lessen this by interrupting the conduction paths between the brain and the field of operation, a principle which he has designated "anoci-association." The three factors concerned are hemorrhage, anesthesia and trauma, of which the latter two are the most difficult to control. The influence of trauma, he finds, can be obliterated by blocking the conduction paths by means of a liberal infiltration with 0.25 per cent. novocain. Bloodgood[24] indorses and confirms Crile's work and urges surgeons to familiarize themselves with the technic by applying it not only to the handicapped patient, to whom it may be the deciding factor of safety, but in daily routine work. He believes this will also add to the comfort of the ordinary individual who can stand considerable operative trauma and bad anesthesia. Bloodgood states that only by the aid of the sphygmomanometer can the surgeon estimate the real significance of the traumatic factor. He finds that there is no change in blood-pressure in operations under local anesthesia so long as no pain is inflicted; and familiarity with recent methods should enable one to obtain a painless operative field in the vast majority of cases. Braun's description of excision of the upper jaw or tongue is a striking example of the protection against shock which local methods afford. As he says, the patients scarcely need to go to bed.

Nowhere is this better exemplified than in surgery of the aged. How many individuals cannot any one of us recall who have been refused the possible benefits of surgery because of age? We can all remember epitheliomas of the lip, in which the lymph-nodes have not been removed, because it was not thought wise to prolong anesthesia; fractures which have been left to vicious or no union; or hernias doomed to the uncertain protection of a truss and the dangers of strangulation. In these cases a mastery of local methods means safety, and by a judicious combination of local anesthesia with a little nitrous oxid at crucial moments the possibilities are without limit.

The removal of cervical lymph-nodes in epithelioma of the lip is so painless as to cause no disturbance whatever. My routine is to infiltrate the neck thoroughly with 0.5 per cent. novocain and then proceed with the excision of the growth on the lip. By the time this is finished and the gloves changed, anesthesia in the neck is so well established that the dissection can be carried out at will. I have done this on a man well along in the eighties and had him walking about next day. In a man of 97 I removed a large epithelioma of the cheek involving the zygoma. This was especially interesting in that a section of Steno's duct was removed and an end-to-end suture made with resulting patency of the duct. The operation lasted nearly two hours and was followed by no shock or depression.

In the treatment of fractures the combined method has been found most useful. Thus in a feeble old lady of 85 with a long, oblique fracture of the shaft of the left femur with great displacement, I was able to expose the bone under infiltration anesthesia. She was then given a few whiffs of nitrous oxid and the fragments brought into line. During the drilling of the bone and the application of the plate, she was conscious and talking, but felt no pain. She was gotten up in a chair the next day and left the hospital in six weeks walking and without crutches or cane.

In hernia operations, I do not consider old age a contra-indication. Hernias of all varieties, I believe, are best done under local anesthesia; and, except in very young children, I recall no case in which it has been necessary to resort to narcosis in the last few years. My oldest patient, a man of 98 with a strangulated inguinal hernia, was operated on over a year ago, the bowel in good condition. He made a good recovery and is now pursuing his work as an artist. In a woman of 84 with an eight-day strangulated hernia with gangrenous small intestine, a two-stage operation was done. The bowel was first brought out and opened, and on the following day her condition was so good that a resection and Murphy button anastomosis was made. Her recovery was uneventful.

In presenting this review of the literature of the last few years, I have by no means exhausted or done justice to the material, but have tried to give some idea of the general progress. I have endeavored to point out some of the possibilities and to show the degree of perfection which can be obtained by such skilled masters as Braun, Bier, Härtel and others.

In this busy American life of ours, I cannot believe that many of us will ever take the time or have the patience to attain that degree of skill. I hope, however, that some of us may persevere and be rewarded by finding how much ease comes with experience. As Bloodgood states, in speaking of Crile's work, the technic cannot be mastered by restricting its employment to handicapped patients, who are too few to give sufficient experience. The details should be learned by daily experience where absolute success is not so imperative. Above all, I trust the method will not in the future be condemned, as it has been in the past, because of ignorance of its possibilities and inexperience in its application.

1344 Nineteenth Street N. W.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. HERB, SLOAN, PECK, MITCHELL AND BOOTHBY

Dr. Carroll W. Allen, New Orleans: As early as 1889 Dr. Matas introduced a method for reaching the second division of the fifth nerve by passing the needle into the orbit, hugging the bone at the lower external angle and directing the needle slightly inward. It enters the sphenomaxillary fissure, passes backward a distance of 5 cm., in the orbit of an adult, and then is exactly under the foramen torundum. I have used this method for blocking the second division of the fifth nerve. I have had ten or twelve cases in which the entire jaw was removed. When the needle is passed 0.25 cm. further back, it reaches the third division of the nerve The methods introduced by Offenhaus and by Härtel exemplify the more notable progress made in this field lately. Härtel produces a small area of anesthesia on the cheek and introduces a needle about 5 cm. in length upward, forward and backward.

Dr. Karl Connell, New York: I believe that the use of alkaloids before anesthesia is entirely unnecessary unless one is using an anesthetic like nitrous oxid. I do not believe that nitrous-oxid-oxygen anesthesia is preferable to ether. The results, so far as Gwathmey and I have gone, show quite the contrary. The ether blocks shock far better than pure nitrous oxid. Intratracheal anesthesia is one of the most highly advanced methods now in use. It causes beautiful oxygenation, carries the patient without shock and permits positive pressure, if desired, and the highest degree of artificial respiration; but the chief advantage in the average case is that it permits one to carry the anesthesia absolutely on the lowest percentage for that particular person and that particular type of operation. As Dr. Boothby said, one can carry along the anesthesia for hours, possibly days. Ether percentage has come to be an important factor in giving an anesthetic, because it is desired not only to put the patient to sleep promptly, but to keep the patient asleep for as long a time as necessary, even hours, with the use of a minimum amount of ether. The level, as it is called, should be maintained in every case. When the operation is completed, the patient should wake up promptly; in fact, he should be practically out of the anesthesia.

Dr. Evarts Graham, Chicago: We have learned that ether is perhaps indirectly responsible for some of the various postoperative or postanesthetic complications with which we are familiar, such as thrombosis, embolism, various lung complications, shock and acute dilatation of the stomach. It should be further desirable to attempt to devise an arrangement by which the ether will maintain its toxic action on the body the shortest possible time. This concerns also the problem of elimination of ether. Even after a short ether anesthesia the smell of ether may be detected in the breath of the patient for a number of hours afterward, so that even under ordinary circumstances ether is slowly eliminated from the body. Now, if we desire to increase the rapidity of elimination of ether from the body, we must consider first of all the channels by which it is normally eliminated. Ether is eliminated in large quantities through the lungs. It also gains entrance to the alimentary tract. The vomitus even after a short anesthesia smells strongly of ether. The ether also escapes through the skin, and part of it gets back into the alimentary tract and is reabsorbed. A period of hours is necessary to eliminate all of the anesthetic from the body. If we can step in somewhere on this circle and drive out the ether in some other way than occurs naturally, we may prevent some of these distressing postoperative complications. The fact that ether is more soluble in fat than it is in water is evidence that such a process can occur; by placing fat in the alimentary tract we can hold the ether there and prevent its absorption from the intestine. If two dogs of the same weight are given through a stomach-tube the same amount of ether, in one case diluted with the same amount of water, and in the other with an emulsion, the dog which receives the ether and water, if it does not vomit up the mixture, becomes deeply anesthetized, often sufficiently to kill it, whereas the dog which receives the mixture of ether and fat not only does not vomit, but is in no wise affected by the ether. This shows conclusively that the fat has prevented the absorption of the ether. Advantage has been taken of this fact in the clinic. For the last year or two I have administered fat in the form of olive oil after the anesthetic was stopped. I found that not only is the postanesthetic period shortened, but there is also less vomiting, in spite of the statements to the contrary which one occasionally finds in the literature, based on mere conjecture and not on experimental proof.

Dr. Harry G. Sloan, Cleveland: The experiments carried out by Crile and *Prendergast* were as follows: Ten dogs were taken in each of two groups. The first ten were given ether, and shock was produced by rubbing the peritoneum for three hours. The second group were given nitrous oxid, and shock was produced in the same manner as in the first group. Blood-pressure tracings were taken to determine the reaction. The ether dogs showed at the end of three hours an average blood-pressure of 10 mm. of mercury, whereas the nitrous oxid dogs showed a pressure of 110 mm. of mercury. Surely a great difference! The ether was given by the open drop-method, not the intratracheal method. I do not see that there is any great difference *in the method of administration*, for anesthesia occurs *only* when the blood-stream contains a certain percentage of ether. In shock, the brain transforms its latent energy into nerve impulse in response to traumatic stimuli; its cells become exhausted. Ether anesthetizes by lipoid solution. Nitrous oxid anesthetizes by inhibiting the intracellular use of oxygen, so that we have two directly contrary principles at work. Under nitrous oxid the functional activity of the nerve-cell is curtailed; hence exhaustion is much more slowly reached than under ether when oxidation is normal.

VACCINE THERAPY FOR GENERAL PRACTITIONERS *

JOHN H. RICHARDS, M.D.
NEW YORK

The first record[1] of induction of active immunity for therapy was about two hundred years ago when it was learned that the orientals were practicing immunization against small-pox by means of inoculation of a little small-pox virus under the skin. From this rather hazardous procedure developed the use of the less dangerous and milder virus of cowpox by Jenner[2] in 1796. The next work of importance was that of Pasteur,[3] who developed a mild and at the same time an immunizing attack of anthrax by inoculating animals with anthrax bacilli which had been grown at a temperature of 43 C. (109.4 F.). Since this advancement many different methods of active immunization have been developed. These methods have been well classified by Bolduan[4] as follows:

1. *Living Cultures of the Virus:* Usually the cultures are attenuated, but there are some exceptions. A number of different methods have been employed for the attenuating of the virus, thus: by drying, as is done with the rabies in the Pasteur[5] treatment; by growing the virus at a temperature that is unsuited to the development of virulence, as is done in the case of anthrax;[3] by passing the virus through a less susceptible animal as is done in small-pox;[2] by means of chemicals such as the addition of iodin to diphtheria toxin, as was formerly done by von Behring;[6] or by means of heat as was formerly done with diphtheria toxin.
2. *Dead Cultures of the Virus:*[7] The cultures can be killed by heat or by the use of chemicals.
3. *The So-Called Combined Method:* This consists of first administering a dose of the specific immune serum and subsequently the virus. This method has been used in typhoid, cholera and plague.
4. *The Products of Autolysis of Cultures:*[8] These have been used in diplococcus meningitis and in typhoid, and seem to possess certain advantages over native cultures.
5. *Combinations of Preceding Methods:*

CHOICE OF METHOD

The choice of the various methods of immunization depends on the nature of the virus, and has been decided for us by research workers from time to time. For small-pox we use with perfect confidence a virus that has been passed through the less susceptible cow and purified. For diphtheria we also use with perfect confidence an immune serum. For typhoid we use dead cultures of typhoid bacteria, and for anthrax we use living cultures of anthrax bacilli grown at a high temperature. The reasons for a choice arise from certain particular facts of immunity, and their discussion is out of place in a paper of this character.

IMMUNITY BY MEANS OF BACTERIA KILLED BY HEAT

The interest in this work has been much stimulated during the last few years by the work of Wright.[9] Indeed, it has been activated to such an extent that many drug firms are marketing preparations of uncertain composition and action.[10] These vaccines are all of the stock variety, and are at best inferior preparations. As a rule the instructions for administration are inaccurate or incomplete. For these reasons much negative harm may be done to the patient by the use of too small a dose, or by use of an improper vaccine. Also much positive harm may accrue from the use of too large a dose.[11] There is surely necessity of using a vaccine that is beyond question one of the highest efficiency, and it is needful to administer such a vaccine in a proper manner. There is no exaggeration in the statement that more painstaking care is required in the management of a vaccine case than is required in the management of a case of broken cardiac compensation. In both cases the amount of the dosage of vaccine in one case, and of digitalis in the other, must be regulated by the clinical effect on the patient, and it is just as impossible to foretell the dose of a vaccine required as it is to foretell the amount of digitalis necessary to act, and not overact, without knowledge of and experience with vaccines.

PREPARATIONS OF VACCINES[12]

The first rule in the preparation of a vaccine is this: An autogenous vaccine is always more desirable than a stock vaccine. A stock vaccine may be of no value whatever in the production of immunity in any given case. Even when a number of different strains are used in the preparation of the vaccine, it is most often markedly inferior to autogenous vaccines. If there were certainty that the infecting organism were of the same strain as the one used in the preparation of the vaccine, then such a stock vaccine would approach the efficiency of the autogenous vaccine. Unfortunately many of the most common bacteria differ in different strains in the production of immunity as much as the bichemical characteristics of bacteria of different species differ. It is always best, therefore, when preparing a vaccine, to use a culture from the disease of the patient himself. If, however, it is impossible to obtain an autogenous growth, the best chance of good results is in the use of a freshly made vaccine from a strain of the causative bacteria, in cases this may be taken for granted as in furunculosis.

[11] Allen: Vaccine Therapy, p. 112.

[12] Wright: Lancet, London, March 29, 1902.

To prepare an autogenous vaccine, it is first necessary to obtain a pure culture of the infecting organism. If there is any doubt that the organism grown is the organism causing the disease, then it is necessary to do a complement-fixation test,[13] using the bacteria grown as the antigen. Having obtained a good growth of the disturbing organism, a twenty-four-hour culture is washed off in sterile 0.9 per cent. saline solution. It is best to use slanted mediums for the cultures to facilitate the washing off of the bacteria. This saline emulsion of bacteria must be sterilized, standardized and prepared for dispensing before the vaccine can be given to the patient.

Standardization.—The following apparatus and reagents are necessary: capillary pipet made by drawing out heated glass tubing, clean glass slides free from grease, wax pencil, a polychrome blood-stain and distilled water.

The saline emulsion of bacteria is centrifuged for a few minutes to free it from those bacterial clumps that are not broken up by shaking well. About ½ inch is marked off on the capillary tube with the wax pencil, and blood from a fresh prick on the worker's finger is drawn up to this point. A tiny air-bubble is next drawn in, and then the centrifuged emulsion is drawn up to the mark. This gives us in the capillary pipet equal portions of blood and bacillary emulsion separated by a tiny air-bubble. The capillary pipet is next emptied on a clean glass slide, the contents mixed thoroughly, and spread evenly over the surface of the slide by means of the edge of another slide. The slide is dried and stained with the stain,[14] in the same manner as for blood-smears. The relative number of bacteria and red blood-cells is then estimated by counting at least 500 red cells and all the bacteria found while counting them. In this way it is easy to compute the number of bacteria per cubic centimeter, remembering that there are 5,000,000 red cells per cubic millimeter. Example: If while counting 500 red cells, 100 bacteria are found, the problem is stated as follows:

$$500 : 100 :: 5{,}000{,}000 : x$$
$$x = 1{,}000{,}000$$

Therefore, there are in the bacillary emulsion 1,000,000 bacteria to the cubic millimeter, 1,000 million to the cubic centimeter.

Sterilization.—The emulsion is best sterilized by submerging the bottle containing the now standardized saline emulsion of bacteria in a water-bath at a constant temperature of 60 C. (140 F.) for one hour; 0.25 per cent. (1 capillary drop for 10 c.c.) compound solution of cresol is then added to keep the vaccine free from contamination. Such vaccines are best dispensed in 30 c.c. colored glass bottles, stoppered with rubber caps, so constructed that a hypodermic needle can be forced through, and that, by inverting the bottle, the required amount of vaccine can be drawn into the syringe. The rubber caps should be kept wet with pure compound solution of cresol.

DOSAGE

The dosage of a vaccine is of utmost importance, and the following rules will be of help:

1. The first dose, and the first dose only, is to be decided arbitrarily.

2. The second dose and all succeeding doses must be regulated by the effect of the first dose. Nothing can be more dangerous than an arbitrary increase of the dose of vaccine regardless of the clinical effect of the preceding dose; for two small a dose may be of no value whatever, and too large a dose may diminish instead of increasing immunity.

3. A marked local reaction at point of inoculation following the dose and accompanied by increased severity in the symptoms of the disease and slight or no improvement in the condition of the patient before time for the next dose, indicates that too large a dose has been given. The patient should be through the so-called negative phase by the end of the second day. When the dose is too large the negative phase is too severe and too long.

4. Slight local reaction following the injection, and accompanied by slight or no increased severity in the disease and followed by no improvement in the condition of the patient, indicates that too small a dose has been given. When the dose is too small there is no negative or positive phase clinically.

5. Slight or no local reaction accompanied by moderate, slight or no increase in the severity of the symptoms of the disease and followed by improvement in the condition of the patient indicates that a correct dose has been administered. After such a dose the negative phase is usually of about twenty-four hours' duration, but may be entirely absent. After the negative phase improvement in some or in all of the symptoms should begin, which is the beginning of the positive phase.

6. The second dose after a correct dose has been given should not be given until the negative phase has been well passed. This is usually within from two to four days. In acute illnesses it is well to begin with small doses which are followed by transitory negative phases, when it is possible to give a second dose within from twenty-four to thirty-six hours. In chronic disease it is safe to give much larger doses with the risk of severe negative phases, but in such cases it is necessary that the doses be given not too frequently. The interval between the doses should be increased or diminished in direct proportion to the severity and duration of the negative phase, and the duration of the positive phase, or period of betterment. The amount of increase or decrease in a dose is determined by the negative phase also, but inversely. A severe or prolonged negative phase indicates a longer interval and a smaller dose. It is well to be conservative, and so long as a certain dose produces adequate response, it is advisable not to increase it rapidly even though a larger dose can be given without a too severe negative phase. It is always well to err on the side of too small a dose and too long an interval. In the department of clinical pathology in Cornell Medical College, clinical symptoms have been found of most value in directing the dosage of vaccines.

INDICATIONS FOR VACCINE TREATMENT

As a general rule it can be said that all chronic bacterial disease can with advantage be treated by means of vaccine. Many acute diseases can be added to this list. Allen[16] asserts that there is benefit in nearly every type of known infection. The following is a list of the bacteria that have been advantageously employed in vaccine treatment:

---

[13] Swift, Homer F., and Thro, W. C.: A Study of Streptococci with the Complement-Fixation and Conglutination Reactions, Arch. Int. Med., January, 1911, p. 24. Schwartz and McNeil: Am. Jour. Med. Sc., 1911, cxli, 693. Hastings, Thomas W.: Complement-Fixation Tests for Streptococcus, Gonococcus and Other Bacteria in Infective Deforming Arthritis and Arthritis Deformans, THE JOURNAL A. M. A., April 19, 1913, p. 1208.

[14] Allen: Vaccine Therapy (See index-dosage).

[15] Hastings: Oral communication.

Staphylococcus.—These bacteria differ much in species (*aureus, citreus, albus*) and little in different strains of the same species,[17] so an autogenous vaccine is not always necessary. The staphylococcal diseases treated by vaccines are boils, carbuncles, abscesses, periostitis, osteomyelitis, septicemia and pyemia. The staphylococcus is often a secondary infection in many diseases, such as acne and tuberculosis, and in such cases staphylococcal vaccine should be used in addition to the specific organism. The initial dose of a staphylococcus vaccine in acute conditions is usually from 20 to 50 millions, and in chronic conditions from 100 to 250 millions. The dose may often be gradually increased to an enormous amount such as 10,000 millions.

Streptococcus.[18]—Like the staphylococcus, the streptococcus is found in different species, but unlike the staphylococcus each species differs much in different strains and an autogenous vaccine should be prepared. Abscesses, cellulitis, septicemia, pyemia, erysipelas, recurrent tonsillitis and various joint affections have been treated by means of streptococcus vaccines. The pyogenic, hemolyzing and the green-producing streptococci differ much and should never be used interchangeably in vaccine therapy. The dosage is about one-fifth or one-tenth of that for similar conditions in staphylococcal infections.

Gonococcus.[19]—Torrey[20] and Schwartz and McNeil have done the most work with this organism. After much painstaking experimentation Torrey isolated two strains of gonococcus which have more immunizing effect than other strains. These strains he calls Strain A and Strain C. On account of the difficulty of obtaining an autogenous growth it is advised that these or similar strains be used in the preparation of vaccine for gonnococcus disease. There are no more brilliant results in vaccine therapy than those found in the treatment of gonorrheal arthritis. An initial dose of 20 millions is given and increased according to the clinical results.

Colon Group[21] (including typhoid).—General infections and especially pyelitis and other local infections caused by these bacteria have been benefited by vaccine treatment. Abundant evidence has been furnished by the British and American armies as to the value of these vaccines in the prophylactic treatment of disease.

Tuberculosis.—Practically every type of tuberculous infection has been treated with vaccine in the form of tuberculin, with different results in the hands of different men.

Pneumococcus.—There is no certainty that vaccine is of benefit in lobar pneumonia, but in the chronic pneumococcus infections good results are accomplished. Especially is this true of empyema.

Other bacteria that have been used in vaccine treatment to advantage are Pfeiffer's[16] and Friedlander's[16] bacilli and the bacilli of rhinoscleroma[22] and acne.

Much valuable work has been accomplished in the prophylaxis of plague[23] and cholera[24] and typhoid by immunization with their respective vaccines. The technic is the same for plague and cholera as for typhoid immunization.

Vaccines are for one purpose only, that is, to produce prophylactic immunity and to increase the resistance of an individual by active immunization, and they should never be used to the exclusion of other methods of treatment that tend to limit the extent of an infection. Abscesses should be drained, diet and hygiene must be considered, and vaccines must be recognized as very valuable adjuvants in combating infection.

34 West Eighty-Third Street.

GENERAL ANESTHESIA IN THE SURGERY OF CHILDHOOD *

WILLIAM C. WOOLSEY, M.D.
BROOKLYN, N. Y.

A presentation of the subject of general anesthesia in children has become an annual occurrence of the Section on Diseases of Children of the American Medical Association, and should be a valuable one if it does nothing more than recall to mind the constantly active factor that narcosis constitutes in the morbidity and mortality of childhood's various surgical procedures. In addition to thus refreshing the hearer's minds, it adds from time to time record of the advances that have been made in the technic and practicability of the art, and acts as an incentive to further investigation and study.

The specialist in anesthesia, as in every other branch of surgery, brings forth that which is ultrascientific, often complex, not that he so far lacks in common sense as to expect every practitioner to adopt it, but that, having the ideal in mind, the general standard may be elevated.

Several important physiologic differences between adult and child bear on the subject of general anesthesia. The pediatrist knows them well, but he may not connect them practically with the question of surgical procedure and narcotics. The physical inferiority of evolutionary childhood in terms of resistance makes the young subject especially sensitive to the toxemia of so grave an interference with nature as the administration of a chemical poison to produce loss of consciousness. Despite the presence of what might be considered as healthy life functions, there is in children a marked absence of that acquired immunity which adults attain through contact with their environment. In this light the child has a small physiologic factor of safety.

The proportion of heat-radiating surface to body-weight is much greater than in the adult; the heat-regulating nervous mechanism has not developed to the high plane of efficiency found later in life. Sudden or great loss of heat becomes relatively a much more serious factor. The total volume of blood in the circulatory system of the child is small, so that comparatively minor losses become relatively more serious and dangerous. The general circulatory efficiency and blood-pressure depend more completely on cardiac action, and less on a well-developed peripheral propulsive factor than in the muscular adult, so that slight interference with the cardiac action draws immediately on the margin of safety of the child.

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

The nasopharynx is distinctly smaller in relation to extraordinary respiratory needs[1]; its sensitive lining mucous membranes are easily stimulated to abundant secretion of mucus and its musculature to spasm, particularly about the glottis (recall the glottic occlusion of catarrhal croup and laryngismus stridulus). In the presence of lymphoid hyperplasia these obstructive and exudative factors are multiplied a hundredfold.

In children poorly understood dyscrasias exist, such as the condition called status lymphaticus, the thymus persists, and mechanically, as well as by its hypersecretion, makes for lessened resistance to the toxemia of anesthesia.

When serious accidents do occur in general anesthesia, in the majority of instances it is directly or indirectly the result of carelessness, the confidence of inexperience, or where familiarity has bred contempt and neglect.

It occurs in every discussion of the matter, as it does in literature, that many men see no sense or need for the general warning against chloroform, and especially not in the case of children. Reports such as that of Grayson[2] of three thousand eight hundred chloroform anesthesias in nose and throat work without a death or serious collapse, prompt the promiscuous selection of this drug for such work without giving due weight, in considering the favorableness of the report, to the individual care and expertness which allowed the successful results reported. We all have considerable ego and easily conclude that we can do as well.

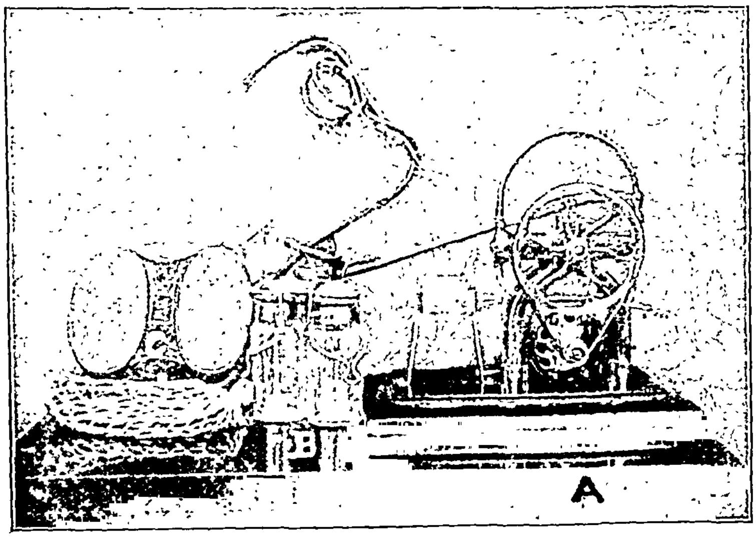

Fig. 1.—Vaporizing bottle set up for tracheal insufflation. *A*, electric motor pump; *C*, foot-pump; *D*, tracheal tube and forceps for introducing; *E*, third bottle of vaporizer used as mercury safety valve.

Chloroform has special advantages when used for children, and particularly in nose and throat work. These advantages prompt its selection by many, even in the face of its relatively great toxicity: 1. It is comparatively safe in the warmer climates. 2. It causes little, if any, increase of the nasopharyngeal mucus in cases in which such mucus dangerously adds to the respiratory obstruction which the operative manipulation inevitably produces. 3. It maintains an anesthesia for a longer period of time after the removal of the cone than does any other agent we employ—this is an advantage to the surgeon. 4. It is easy to carry and practical to administer. Despite all these advantages, however, the well-known and repeatedly demonstrated toxicity of the drug compared with others, makes it an agent to be avoided, and particularly so by the very ones who use it most, namely, the inexperienced, occasional users.

ERRORS OF TECHNIC THAT HAVE CONTRIBUTED TO AND CAUSED HIGH MORTALITY AND MORBIDITY, ESPECIALLY IN ADENOID AND TONSIL REMOVAL

Passing with mere mention the general necessity for minimum dosage of anesthesia and extreme care of administration with children, one comes to an analysis of the technical errors which cause damage or fatality in the usual anesthesia.

In the case of chloroform, its special toxicity has been mentioned, but the error of administration which renders the toxicity active in the hands of the inexperienced has most often, according to my observations, been the continuous dropping, if not pouring on the mask, of the chloroform during the period of apnea, caused by a half voluntary holding of the breath, a spasm of the glottis, or an obstruction in the pharynx from blood and mucus. During this period of apnea the chloroform is collecting in large concentrated dose under and around the mask, lying in wait, so to speak, for the period of hyperpnea which will succeed the apnea, so that with this period of hyperpnea or deep, exaggerated breathing, the toxically concentrated and large volume of drug is sucked into the lungs with resultant paralysis of the central respiratory mechanism. Its threshold for stimulation being so lowered by the overdose of drug that the normal stimuli fail to maintain their influence, and death occurs.

In the case of ether, with its relatively slight toxic effect on the vital nervous mechanisms, the local irritant influence becomes active in producing an exudate of mucus or spasm of the glottis, the which, being greatly exaggerated in cases of lymphoid hyperplasia, becomes, in conjunction with the operative manipulations, a serious source of obstruction to breathing. This obstruction to breathing produces a marked degree of asphyxia in the subject for adenoid or tonsil removal, and at the same time prevents the further inhalation of the anesthetic. Recovery from the anesthetic prompts the anesthetist to apply large, concentrated dosage in order to subdue the patient and in virtue of this irritating dose the state of mucus exudation and pharyngeal spasm is again instituted. Thus is established a vicious cycle of too superficial anesthesia on the one hand, with obstructed breathing and damaging asphyxia on the other. Obstructive apnea alternates with overconcentration and overdosage, and gives an anesthesia than which there could be no more perfect for the inconvenience of the surgeon or more detrimental to the child.

At first glance this condition might seem to apply to cases in which surgery of the throat alone is in question, but the observation of any intelligent anesthetist or surgeon will demonstrate its existence as a cause of trouble in many anesthesias in children. The use of the drop technic in children on an open mask or covered with towels focuses every element of the danger that lies in its abstraction of heat or refrigeration on a subject the least able to withstand bronchial exposure or loss of bodily heat. The virtue of its comparative safety is swallowed up in the risk of its refrigeration. The only excuse for the use of any direct application of the liquid ether to the subject's airway is ignorance on the part of the anesthetist or sacrifice of patient's welfare to the convenience of the surgeon.

---

[2] Grayson: Laryngoscope, 1913, xxiii, 61.

If there be any truth in Crile's observations on toxic nerve assault or anoci-association, we have good theoretical reasons to add to the frequent practical demonstration, that the extreme fear which accompanies many inductions of anesthesia does real damage to the subject's central nervous system and may have considerable influence in instances in which sudden anesthetic collapse occurs. In some cases a child may be anesthetized while asleep, but more often some speedy, sure technic must be adopted to shorten the seconds of agony for parent and subject. For this purpose no doubt nitrous oxid, properly administered, is superior, all things considered, the exception being in very young infants in whom the few drops of chloroform necessary to produce the desired result are less to be feared than the gas. Perfume, or 25 per cent. essence of orange, on the mask, prior to the chloroform, has its advantages.

The preponderance of narcoses in operations for adenoids and tonsils in children and the many difficulties encountered by anesthetists and surgeons in securing satisfactory anesthesia, make its consideration a factor of some consequence. Recently, French[3] has reported some investigations on anesthesias in throat work in children and during the use of the upright position has sought to attain the most satisfactory narcosis with the gas-ether sequence, Dawbarn's sequestration anemia, and an oxygen vapor of ether administered through a mouth tube during the operation and at intervals. The work of the operator is of the slow, painstaking kind, and thoroughness is his watchword, so that the anesthesia is of importance. The nitrous oxid initiation is found wanting in the claimed difficulty of the transition from gas anesthesia to ether. The oxygen ether vapor during the operation is complained of as probably augmenting the bleeding. Nasal insufflation is suspected of damaging the accessory sinuses of the nose.

In opposition to these views I believe that a nitrous oxid initiation is of sufficient value to warrant the acquisition of the skill necessary for the smooth transition from gas to ether vapor, and that such skill can be easily acquired. Also that the marked practical and theoretical value of nasal insufflation through tubes introduced well into the pharynx prompts the selection of this technic and that insufflation so used offers little, if any, chance of damage to the sinuses of the nose. The vapor-delivering mouth-gag, the oral tube, and the nasal tube deliver the anesthetic vapor outside of the area of obstruction to breathing in adenoid and tonsil work and thus do not overcome the respiratory obstructive difficulties of this anesthesia. Where tubes are inserted well below the soft palate, positive pressure within the nasal cavity and damage to the sinuses are negligible factors. The anesthetic vapor is delivered well behind the obstructive difficulties in the upper pharynx and if a proper volume of air is insufflated, the excess in the form of outflow tends to force the blood and mucus forward in the mouth where sponges or suction pump can remove them.

There are two operations especially that are performed on children in which the operator and patient are so handicapped by the mechanical question of anesthesia that I am certain that many deaths result directly because of the anesthetic. These two procedures are for sarcoma of the maxillae, especially the superior, and cleft palate. In both operations long periods of asphyxia are produced by the mechanical manipulation within the subject's airways, and in sarcoma of the superior maxilla especially from the hemorrhage that is bound to occur even with ligation of the external carotid.

INTRATRACHEAL INSUFFLATION ANESTHESIA

Tracheal insufflation anesthesia in children is especially easy of performance and offers such perfect anesthesia without one moment's anxiety for asphyxia or inhalation of blood and mucus, that any surgeon who operates once with its aid certainly would never attack a similar operation without it. The blood and mucus are actually washed out of the nares by the return flow of air, and the constant pink color of capillary circulation testifies to the complete oxygenation; the surgeon's *work is not interrupted by the intermittency of the* narcosis and the subject does not run the gauntlet of dangers from improperly maintained, recklessly toxic anesthesia.

In children the glottis is easily reached by the guiding index-finger of the left hand, the rubber catheter (18 to 22 size, with opening at the end and side) is easily introduced with forceps shown. The tube is then fastened to the angle of the mouth by a suture passed through the cheek and tube, and the anesthesia carried on by even so simple an arrangement as the vapor bottles shown in Figure 1.

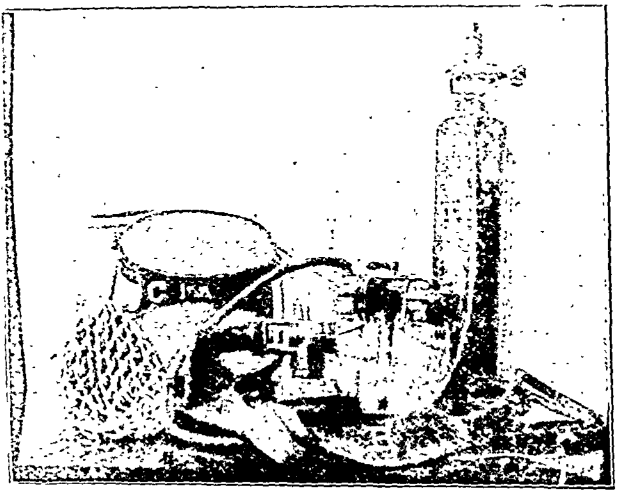

Fig. 2.—Nitrous oxid-ether vapor sequence apparatus. *A*, vaporizing bottles connected with bag *B* at *F*; *C*, foot-pump; *D*, Gwathney-Woolsey gas mask; *E*, gas tank connected with bag at *F*.

ANESTHETIC TECHNIC ADOPTED BY THE AUTHOR

Sedative medication in the form of morphin products, etc., as a preliminary to anesthesia in children comes under the general head of contra-indications in the extremes of life, so that seldom, if ever, is it used.

Initiation of the narcosis is accomplished in as speedy and certain a manner as is consistent with safety, by the selection of one of two methods, viz.: Nitrous oxid gas or the essence of orange (25 per cent.) on a mask, followed by chloroform in carefully administered, intelligently observed dosage. These are followed by ether, in some way vaporized at a distance from the little patient's airways.

The gas-ether sequence is to be preferred if handled in a proper manner, and to be condemned if not so handled. The chloroform-ether sequence is safer than a poorly administered gas-ether. The technic which I use is the following:

---

[3] French, T. R.: New York Med. Jour., 1913, xcvii, 1061.

The Gwathmey vaporizing bottles (A, Fig. 2) are properly filled with ether and water; 1 dram of essence of orange (25 per cent.) is placed in the water bottles. The foot-pump of the type shown (C, Fig. 2) is attached to bottles and from these to the lower end of the small breathing bag (B) and at this same point is attached a tube from a small tank of nitrous oxid. The bag is filled three-quarters full of gas; the mask (D) is placed quickly over the little patient's face, and in fifteen seconds unconsciousness ensues. After two breaths of gas have been taken, the foot-pump forces the weakest of ether vapors from the bottles into the bag where, like the gas, it is rebreathed, only a slight expiratory escape being allowed. This continues until deep ether narcosis ensues, at which time the breathing bag and mask are thrown aside and either a small vapor delivering Yankhaur mask is applied and connected with the bottles, or nasal tubes are inserted to the deep pharyngeal space. In either case, anesthesia by a nonrefrigerating, minimum-dosed technic is continued. In ordinary anesthesia, that is, where access to the mouth or face is not needed, a towel or two, thoroughly covering the mask and confining the tidal air, gives the subject the benefit of considerable rebreathing with its carbon dioxid beneficence.

The ether indicator on the vaporizer rarely, if ever, goes above half way between ether and air. Instead of the foot-pump a stream from the oxygen tank may be used to carry over what ether vapor is needed, especially in those grave risks which test the skill of every surgical procedure.

The vapor method of administering anesthesia, including as it does such procedures as the pharyngeal insufflation recommended a year ago at Atlantic City by Dr. Pinneo, of Newark, N. J., and the tracheal insufflation for special surgical work, is one extremely easy of application, and because of its many virtues should be more generally adopted. An ordinary cautery bulb attached to a wash bottle of ether is superior to a drop technic on an open refrigerating mask and can be arranged by anyone without noticeable expense.

TECHNIC FOR ADENOID AND TONSIL WORK

As in any case initiation of the anesthetic is accomplished with the nitrous oxid-ether sequence, given as described above, and at the point where the breathing bag is thrown aside one or two soft rubber catheters are introduced through the nose and into the pharynx a distance equal to that from the external auditory meatus to the nares so that their ends rest just above the glottis, ether is thus insufflated to a point behind the obstruction of blood, instruments and fauces, and anesthesia is maintained by means of the foot-pump or the electric motor and pump (Fig. 1). The use of this latter means of air-supply furnishes coincidently one of the most valuable features of the technic, namely, a combined suction tube and tongue depressor. This suction tube, attached as it is to the air intake of the motor pump, and having an ordinary aspirating bottle between it and the pump, acts as a perfect aspirator of the throat contents during the operation, giving a clear field of vision to the operator and assisting materially the anesthesia by further freeing the airways of obstructing blood and mucus.

The vapor-delivery tube attached to a mouth-gag fails fully to maintain the narcosis because it delivers its anesthetic outside the obstructed area, and having the anesthetic vapor as strong as possible or in as large quantity as can be produced, avails nothing, inasmuch as the throat is obstructed at the fauces.

Nitrous oxid and oxygen as an anesthetic for adenoid and tonsil removal is not generally satisfactory, for the reason that it requires cumbersome apparatus to supply the large volume of gases needed in rendering them effectual through the nose; it produces a degree of cerebral congestion very productive of hemorrhage, and operator and anesthetist must be not only trained to work together, but in sympathy with each other's efforts and shortcomings.

RESPIRATORY RESUSCITATIVE MEASURES IN ANESTHETIC COLLAPSE

The very great majority of anesthetic deaths in both adults and children are of respiratory origin primarily, and in such accidents our efforts toward revival have been in no minior degree trivial. Artificial respiration as performed by the old recognized Sylvester or Shaefer methods has served well in some comparatively few cases, but its limitations are many. Oxygen, applied as it ordinarily is, by means of a tube placed in the nose, a funnel over the mouth, or similar procedure, almost provokes a smile when one realizes the state of the glottis, respiratory center and lungs when such collapse has occurred.

During a faulty narcosis with varying degrees of obstructed breathing, often progressively worse as the anesthesia proceeds, there is a constant negative pressure created within the chest by the violent muscular effort to obtain air through the obstructed throat, and when this continued asphyxia finally ends in respiratory collapse the epiglottis is so firmly sucked down against the vocal cords that its elevation by the finger is like pulling a cork out of a bottle; holding the jaw forward, even traction on the tongue under these circumstances is absolutely ineffectual in raising it, so that the ordinary artificial respiration with oxygen delivered outside the obstruction (in the mouth, for example) is next to useless. This condition of glottis and epiglottis was noted in utilizing the endotracheal tube for resuscitation of patients whom intern-anesthetists in hospitals had paralyzed, and in the presence of such physical conditions I believe that tracheal intubation offers the best means of quickly instituting artificial respiration in anesthetic collapse.

Another interesting phase of endotracheal artificial respiration has been developed in newly-born infants of atelectatic disposition where breathing has failed to materialize under the ordinary gymnastic manipulations. Any pediatrist who has used the O'Dwyer tubes can insert a small rubber, stiletted catheter into the glottis of a child without even the difficulty attending ordinary intubation, and though a mercury safety-valve between the oxygen tank and lungs is a primary requisite, emergency occasions could be met by a careful manipulation of the oxygen stream through the ordinary water bottle or a foot pump. Meltzer's recently described respiration valve effectually interrupts the stream of insufflated air or oxygen. This procedure in anesthetic collapse, sedative drug or gas poisoning, and post-partum atelectasis is a distinct advance in the means of resuscitating respiratory failure.

88 Lafayette Avenue.

Metabolism and Dietetics.—The whole subject of metabolism and its relation to dietetics reminds one somewhat of working out a picture puzzle, where not only one picture has been cut up into intricate shapes, but where numerous pictures have been cut up and confused. One worker fits in his little bit, and another his, and a third likewise, and so on, and then some one else discovers that two different pictures are being confused; and so the work goes on until every now and then the master mind comes along and groups the discovered bits aright.—Friedenwald and Ruhräh, "Diet."

HYDROTHERAPY IN NERVOUS FATIGUE [*]

CURRAN POPE, M.D.

Medical Superintendent, the Pope Sanatorium; Neurologist to the Louisville City Hospital

LOUISVILLE, KY.

Fatigue may be defined as an exhaustion of the bodily, nervous or mental powers, or of all combined. In the neural fatigue that we are to consider, it may be stated in broad terms that the person suffers in all the various spheres mentioned. Fatigue in the normal subject is not unpleasant, but a rather delightful preface to restful restoration.

The chemical conditions of fatigue lie in the production of the so-called "fatigue substances," particularly carbon dioxid and lactic acid. These substances in small quantities increase protoplasmic activity and augment muscular energy. The preponderance of evidence seems to favor the idea that there is a high degree of resistance to fatigue on the part of the brain and spinal cord, as well as the nerve fiber itself.

Fatigue is a general systemic sensation like hunger and thirst; it has its localized sensations, more especially in the eyes and muscles. Fatigue may become so overbearing as to become painful and destroy the desire of life. Brunton[1] says that so long as the muscles are connected with the central nervous system complete exhaustion of the muscle is impossible, for before it becomes paralyzed by its own exertion, the sensation is perceived by the nerve-centers and the nerve stimuli, which proceed to the muscle, are so much diminished that complete paralysis is never produced. The sensation of fatigue is perceived in the central nervous system but is produced by peripheral exertion. Fatigue is overcome only by the removal of those products that are the causative factors of the condition, and is therefore a matter of the relative balance between available energy and the resistance against which this energy must work.

We must clearly distinguish between genuine fatigue and that pseudo fatigue which results from a lack of the habit of industry. As Lee[2] has remarked, "most of us work too briefly and rest too long." Offner[3] well remarks that subjective symptoms offer an unreliable measure for fatigue, which he was able to substantiate by a study of physical and mental tests. The normally fatigued nervous system of one who has not made great drafts on that wonderful neural reservoir of which William James[4] speaks protects itself by seeking rest and recuperation, and it is now a fairly accepted belief that we often rest because we do not wish to be fatigued.

That the mental attitude has a great deal to do with the question of perception and feeling of fatigue is a well-known fact. The power of music to quicken the steps of the tired soldier, the influence of the emotions in redoubling one's strength, and the driving force of reward displace the feeling of fatigue in many instances. We instinctively feel that fatigue calls for rest; our minds become impressed with this fact and the continued consciousness of the fatigued state serves to intensify the consciousness to a greater or less degree, depending on the suggestibility of the individual.

CAUSES OF FATIGUE

Many writers assign our complex civilization as the main cause of neural fatigue, but I would prefer to say that neural fatigue more often results from a lack of adaptability than as the direct effect of civilization on the central nervous system. It is improper mental work *accompanied* by irritation and worry rather than mental work *per se* that breaks one down. Muscular overexertion can undoubtedly bring about neural as well as mental fatigue, owing to the intimate physiologic connection between the central nervous system and muscular groups; in fact it is not a muscular proposition, but a neuromuscular one. Those who have had occasion to observe an athlete after strenuous exertion, a Marathon, or a six-day bicycle race, have noted in this strong healthy person physical and mental symptoms similar to those seen in the neuroses and psychoses. It may be interesting here to note that muscular fatigue is much more quickly recuperated from than that fatigue which results from prolonged mental strain and worry. When one's labor is pleasing and performed without internal mental friction, the work may be kept up for many months and years without nervous tire, whereas half the same amount of labor that is disagreeable will be prone to produce nervous breakdown and imperfect work. Labor unsuited to the individual is more apt to provoke fatigue than that for which he is specially fitted. If to these conditions of occupation be added insufficient hours of rest, worry, anxiety and the lack of home peace, we may expect nervous fatigue. While I believe that the sexual sphere may be productive of many cases of nervous fatigue, still I do not believe that it occupies the somewhat exaggerated position that certain writers seem to give it.

CLASSIFICATION

I would classify nervous fatigue as follows:

1. Fatigue resulting from inherent nervous weakness; hereditary factor.
2. Fatigue resulting from retained metabolic wastes; non-oxidative factor.
3. Fatigue resulting from toxins; non-eliminative factor; (*a*) endogenous; (*b*) exogenous..
4. Fatigue resulting from circulatory defects.
5. Fatigue resulting from organic diseases.

1. Fatigue resulting from inherent nervous weakness. Persons in this class are doomed by hereditary entailment of an unstable nervous system to a life of neural fatigue. They are persons who seem to "short-circuit" their nerve force and are thus "usually run down"; who live an existence on a narrow margin and are constantly making overdrafts on their limited capital.

2. Fatigue resulting from retained metabolic wastes. In this class we find a large number of persons whose metabolic processes, eliminative organs and tissues seem to be inadequate to the demands of caring for the removal of the normal or pathologic wear and tear of the body. A failure to oxidize these waste products is probably largely due to a disturbance of the so-called "internal secretions"; the secretions from the various ductless glands stimulate the removal of waste and favor cell reconstruction. An active circulation for the removal of waste products is a *sine qua non*, and the influence of hydrotherapy in developing a flexible circulation enables us to bring about brilliant results in these cases.

3. Fatigue from toxins, endogenous and exogenous. A great many, if not the majority of toxins, especially the putrefactive varieties, are produced chiefly in the intestinal canal, and a moderate sterility of this system

---

[4] James, William: Energies of Man.

is undoubtedly of great advantage in nervous fatigue. The presence of indol, skatol, phenol, ammonia and other toxic products, to say nothing of the toxins arising from the various bacteria themselves, must be promptly removed. That weariness may be produced by the direct action of these chemical substances on the brain itself and on the motor nerves and muscles is now accepted by many authorities. It is in this way that neural fatigue is often brought about. Bernheim[5] believes that the toxin or toxins circulating in the blood have a special affinity for certain tracts in the nervous system and that this is frequently revealed by exaggeration of tendon reflexes, and further, that the toxic factor often underlies a case that is supposed to be due to some emotional shock, physiologic strain or passing infection. He says that suggestion may aid the functional elements, but is powerless against the underlying dyscrasia of the nervous system.

4. Fatigue resulting from circulatory defects. A failure of circulatory activity is frequently an added cause of fatigue, supplementing the effects of imperfect metabolic functioning and the formation and retention of toxins of all kinds. This may produce a state of hypertension or a great variation of blood-pressure, which is sometimes abnormally low, sometimes abnormally high.

5. Fatigue resulting from organic disease. Neural fatigue resulting from organic defects will, in a given case, depend on those pathologic changes that constitute the disease. Among the most common of all the underlying organic diseases that produce general nervous fatigue must be mentioned arteriosclerosis,[6] in which the sclerotic or fibrotic changes shut off the quantity of blood to the part, depriving it of the power to nutritionally care for itself. That many other organic diseases produce fatigue and exhaustion is well known, but the foregoing paradigm will serve for the purpose of calling attention to the necessity of carefully eliminating this factor in the diagnosis of fatigue conditions.

DIFFERENTIATION

It is not possible to separate nerve fatigue according to its causation, save in rare instances. It is well to bear in mind that nervous fatigue is an exceedingly complex condition and that the foregoing causes frequently combine, though one of these conditions may be so predominant as to make it the principal or real causative factor in the case.

SYMPTOMS

Pathologic nervous fatigue is induced by minimal exertion, or an exertion that would fail to produce exhaustion in a normal person. Fatigue, lassitude and exhaustion when established are present even without exertion, and the fatigue is increased by physical as well as mental activity. Fatigue is nearly always associated with a more or less marked emotional condition. Fatigue, irritability, emotionalism and generalized mental depression form the characteristic basis of nearly all cases of nervous fatigue. The diagnosis of neural fatigue is often made when the symptoms are really due to an underlying organic disease, like tuberculosis or syphilis. Even neurasthenia is not a correct term to cover all cases. Nervous fatigue is very common; genuine neurasthenia, as compared to the number of cases so labeled, might be designated as rare. A much closer restriction of this designation would be beneficial to both physician and patient.

METHODS

The methods to be employed in the treatment of nervous fatigue naturally fall under two categories:

1. General systemic measures, the aim and object of which is to remove the underlying causative conditions and to tone, strengthen and reconstruct the nervous system.

2. Local measures for the palliation or relief of localized symptoms.

Each of these can be further subdivided into (1) general systemic measures (*a*) in the home and (*b*) sanatorial; (2) local measures (*a*) in the home and (*b*) sanatorial.

It is my belief, perhaps based on personal experience and not perhaps without bias, that private hospitals or sanatoriums offer the best places for the treatment of these patients.

Hydrotherapy is by far the most important of all the physical measures used in the treatment of nervous fatigue. Long experience has led me to the belief that, were I limited to one method alone for the management of this disorder, I would unquestionably choose hydrotherapy. The hydriatic prescription can be intelligently applied to the patient only when it is based on a thorough diagnostic knowledge of the practical case in hand. With this as a basis and a thorough knowledge of the physiologic action of hydrotherapy and its associative procedures, we are then in a position to "temper the wind to the shorn lamb." It is my opinion that the nervously fatigued do best in some small institution, thoroughly equipped, owing to the needs of complex apparatus, by means of which the various forms of douche can be administered, and to the further fact that the physician in this line of work acquires a knowledge and experience that enables him to readily meet the problems that arise in every case of this disorder.

Hydrotherapy strikes at the root of the trouble; endeavors to remove the underlying cause by physiologic action, lessens nerve sensitiveness, invigorates and strengthens nerve processes, and raises the general mental feeling of buoyancy. In cases of nervous fatigue, the treatment must be persisted in for some time, from three to six months or even longer. It has for its object not alone the relief of the fatigue, but also a reconstruction that will resist morbid influences after the patient returns to his former life. It must be borne in mind that the douche to the spine, under various pressures, is a powerful agent in arousing weakened spinal centers to activity; it develops wide-spread spinal reflexes, improves the nutrition of the cord and centers, by strong fluxive or hyperemic results, to the starved and irritable centers. Few cases are so simple that they do not require a combination of methods.

The principles that underlie the treatment of nervous fatigue by hydrotherapy and its procedure, together with the methods that can be employed, follows:

1. A preliminary sweating procedure. This draws the blood to the surface, stimulates glandular activity and prepares the patient for the cold application. Methods: Full dry-pack, full wet-pack, vapor or steam; heat, superheated dry hot air, full bath and incandescent electric-light bath. The last-named is undoubtedly the best.

2. A warm application. The warm water cleanses the skin by its mecnanical effect, increases the dilatation of the blood-vessels and prepares the patient for reaction. Methods: warm full bath, rain bath, needle bath,

---

[5] Bernheim, L.: Rev. de méd., Paris, 1909, xxix, No. 4.

[6] Pope, Curran: The General Physiologic and Therapeutic Action of Hydrotherapy, Jour. Advanc. Therap., May, 1908.

douche (fan, spray, jet and Scotch), especially applied to the general body surface, spine and liver.

3. A cold application. This is tonic, reconstructive, eliminant and rejuvenating. In the nervously fatigued this should always follow sweating procedures and warm applications. Object: to train patients to stand strong pressures and cold temperatures, which should always be brief. Methods: sponge, affusion, dripping-sheet, half bath and affusion, shower, rain-bath, needle and douche (fan spray, jet and Scotch).

4. Reaction. This is the absolute essential and fundamental necessity of all hydriatic methods in the treatment of nervous fatigue. Reactions is that sense of glow, stimulation and feeling of pleasure and comfort, combined with a pinking of the skin, a general tonic state of the circulation on the surface, etc., that follows a moderate application of cold.

5. Brevity. All forms of treatment in nervous fatigue should be brief. They should commence with the shortest possible duration, of the mildest temperatures and lowest pressure, all of which are gradually increased. When the maximum application is reached of temperature and pressure it should still be encompassed under the term "brevity."

6. Frequency. The applications may be made from three to six times weekly, best in the forenoon, from two to three hours after eating and usually followed by rest.

7. Patients do best on a combination of methods; for example, an electric-light bath, followed by warm or hot rain-needle, fan or jet, rapidly reduced to a lower temperature, and this in its turn followed by a cold anal douche for constipation. In my experience, which covers the range of drug, mechanical and so-called physiologic methods, I have never yet found anything to equal the rain, needle and jet douche.

PLANS OF TREATMENT

Plans of treatment may be divided into those that may be employed (*a*) at home and (*b*) at sanatoriums. I have already[7] outlined these as follows:

(*a*) A plan suitable for the home or for those whose reaction is poor would be the following: Dry-pack for from one-half to one hour, followed by a cold sponge with water at a temperature of 70 F. for three minutes, with vigorous friction. As soon as this point is reached dispense with the dry-pack and give the dripping-sheet at 65 F. for three minutes, with good friction, while the patient stands in a foot-tub of water as hot as can be borne. Reaction must be secured. This treatment is generally administered in the morning, and when this time is selected give the general wet-pack at 65 F. for one hour at bedtime. When the patient is removed from the pack he is rapidly dried and no reaction is sought. The advantage of this method of treatment is to obtain the stimulating and tonic influences of the dripping-sheet in the morning and the sedative and sleep-producing effects of the wet-pack at bedtime.

Another good method is to have the patient sit in a half bath with water at from 102 to 104 F., while the attendant gives him an affusion at 80 F. At this point the patient should stand in the tub in water as hot as can be borne, while the affusion is given to the entire body, or the water is thrown with force against the body from a large dipper. This may be further modified by first immersing the body in warm water, then giving a salt rub or glow, followed by the affusion. The warm full bath (104 to 105 F.) for five or seven minutes, followed by the salt rub and finally by the cold shower at from 70 to 65 F., will be found useful. Reaction is essential.

(*b*) "In *institutions or sanatoriums* many women and nearly all men may *commence* with the following, particularly if the patient is up and going about: Electric-light bath or hot-air bath until perspiration commences, followed by the circular or horizontal rain-bath at from 100 to 104 F. for one and one-half to two minutes, reduced to 75 F. for one-fourth minute, with a pressure of 20 pounds. Reduce the temperature 2 degrees daily to 60 F. and increase the pressure 2 pounds daily until 30 is registered. After about a week of this treatment we may add to the foregoing the fan douche at a temperature of 60 F. to the entire body for from five to ten seconds. The next move should be the following: Electric-light or hot-air bath until perspiration take place, followed by the horizontal or circular rain-bath at 100 to 104 F. for one minute, reduced to 60 F. for from fifteen to twenty seconds, pressure 30 pounds, to be followed by the jet douche to the spine and legs at 60 F. for five seconds. An excellent method of treating these cases after reaction has been well established is to apply the jet douche to the spine at a temperature of 105 F. for a half to one minute, followed by the jet to the spine at a temperature of 60 F. for ten seconds, increasing the temperature of the hot water 2 degrees daily until 110 or even 120 F. is reached, at which point it will usually be found that the patient can tolerate no higher temperature. This is especially useful in men who are physically strong and who complain of persistent "head feelings" and tender spine. Neurasthenics do not, as a rule, stand the Scotch douche well. Certain prominent symptoms often demand special attention.

MEETING SPECIAL SYMPTOMS

Hydrotherapy offers a fertile field for the meeting of the various symptoms, objective and subjective, that occur in nervous fatigue.

Insomnia. The insomnia can best be met by the cold-pack or dripping-sheet at bedtime, or the so-called "Neptune's girdle" or trunk compress, consisting of a coarse linen bandage wrung out of water at a temperature of 65 F. and covered by several layers of the same material to exclude the air. It should be worn all night. A most excellent method is the neutral bath, temperature from 94 to 96 F. for from twenty to sixty minutes. Simple measures that sometimes produce sleep are the use of Chapman's ice-bag to the spine, or a hot and cold spinal sponge. In addition, we may give from 6 to 12 ounces of warm milk on retiring, either plain or predigested. A short foot-bath should be given.

Headaches and head pressure. For headaches and head pressure the fomentation applied for five or ten minutes twice, and followed by a cold compress, is very effective. If the headache is congestive, the hot foot-bath should be used, followed by the ice-bag to the nape of the neck and the cold compress to the forehead. Sitz-baths at 90 F., reduced to 65 F., or cold foot-baths, will often give relief. If the headache is persistent, indefinable and annoying, it can sometimes be permanently relieved by means of the Scotch or alternate douche to the spine and legs.

"Spinal irritation," so-called, or the "neurasthenic spine," is best met by general douche treatment to the spine. When this is not effective, the Scotch douche at from 120 to 125 F. for thirty seconds should be used, followed by a temperature of from 50 to 60 F. for from five to ten seconds, with four alternations. Sometimes the hot and cold spinal sponge at bedtime is successful.

For *eye pains* and *muscae volitantes* the fomentation to the eyes and forehead should be employed, followed by the cold compress for half an hour, repeated, if necessary, several times daily.

For *ovarian irritation* and *vaginal discharges,* hot vaginal irrigation should be used daily or twice daily, and hot trunk pack applied sufficiently low down to include the pelvis and hips; that is to say, to the middle of the thighs.

---

[7] Pope, Curran: Practical Hydrotherapy, Cincinnati Medical Book Company, 1909.

Sexual irritations can often be promptly relieved by the hot sitz-bath from 110 to 115 F. for from five to ten minutes, followed by the cold jet douche to hips and lower spine for fifteen seconds.

Menstrual delay and pain are best met by the hot sitz-bath from 110 to 115 F. for from ten to fifteen minutes, followed by cold affusion over the hips. The warm (not hot) vaginal douche favors the commencement of the period.

For *anorexia,* a glass of ice-water should be given one hour and the ice-bag applied for half an hour before meals. It is astonishing sometimes what results will follow this simple treatment.

For *dyspepsia nervosa* the patient must be placed on general treatment, although the trunk pack at a temperature of 65 F. for one hour is sometimes helpful.

Rectal irritation and *constipation* are greatly benefited by the use of the perineal and anal douche as hot as can be borne, followed by a cold douche of from 60 to 50 F.; stronger revulsive effects may be obtained by an alternate hot and cold application.

Colitis and *intestinal catarrh* are best met by means of the dripping sheet, followed by the sitz-bath from 70 to 65 F. for from three to ten minutes, during which time the attendant and patient rub the abdomen and hips thoroughly.

Gastro-enterocoloptosis is best met by an abdominal supporter and the Scotch or alternating douche to the abdomen, under weak pressure, gradually increased. The temperatures may be increased and decreased gradually.

Backache is often promptly relieved by the jet and Scotch douche or, what is better than all others, the Scotch jet douche.

Vertigo is best met by general treatment and the hot and cold jet to the spine.

PREVENTION

Prophylaxis and the maintenance of health after recovery are best secured by a combination of factors, of which hydrotherapy is the most important. A person who has been nervously fatigued should try and adapt himself to reality and to the work he has to do. All
hygienic measures and the consistent and persistent minial
of cold water will maintain a degree of heal produce
little short of surprising. As I hav ssitude and
remarked, it would be far better for even without
purchase a good shower bath than man physical as
pieces of bric-a-brac that frequently ly always asso-
form many disharmonies. ional condition.

The aim of the treatment has been eneralized men-
factors, to stimulate the metabolic pr sis of nearly all
and change the pathologic state to a of neural fatigue
times health has been obtained even really due to an

forces and makes much more efficient
tion that we may care to administer
the hydriatic method.
become more effective

absence of acne is noticeable, especially in epilepsy; hydrargyrum bcomes much more effective and rapid in its action in syphilis; smaller doses of hypnotics are required for insomnia; drug habitués and alcoholics require smaller doses and finally tonic (that is, cold) hydrotherapy requires a much lessened quantity, as well as number of drugs, in the medication of gastric disorders.

REMARKS

Condemnation of unscientific hydrotherapy cannot be too strongly urged. "How many crimes, O Hydrotherapy, have been committed in thy name!" To this there is no answer. From a considerable acquaintance with users of hydrotherapy, I am inclined to believe that the greatest danger lies in the lack of a real diagnosis, the separation of the sheep from the goats. With a knowledge of its action not alone in nervous fatigue, but also in a whole host of disorders and diseases, a failure to use it is, in a sense, a medical crime. It is too valuable and important a remedy, too far-reaching and useful, to be relegated to the charlatan, quack and that abomination of all hydriatists, the "giver of baths." Hydrotherapy belongs to the medical profession; it is a scientific measure, capable of scientific application, and must never again be allowed to drift to destruction on the rocks of therapeutic nihilism.

CONCLUSIONS

1. Nervous fatigue is a complex state of mind and body, largely toxic.

2. Its origin is due to an inability on the part of the individual to adapt himself to heredity, environment and reality.

3. Its symptoms are many and occur as an entity or in conjunction with many other disorders and diseases.

4. Hydrotherapy is an ancient measure, universally found, possessing cleansing, antiseptic, thermic and mechanical powers.

5. Its physiologic action on the human body is largely brought about through disturbing influences of temperature, and mechanical effects on peripheral sensory nerves.

6. Brief applications followed by reaction do not particularly affect temperature.

7. In that will [illegible] is increased on the surface by heat,
ient returns to his former life. It must be borne in mind that the douche to the spine, under various pressures, is a powerful agent in arousing weakened spinal centers to activity; it develops wide-spread spinal reflexes, improves the nutrition of the cord and centers, by strong fluxive or hyperemic results, to the starved and irritable centers. Few cases are so simple that they do not require a combination of methods.

The principles that underlie the treatment of nervous fatigue by hydrotherapy and its procedure, together with the methods that can be employed, follows:

1. A preliminary sweating procedure. This draws the blood to the surface, stimulates glandular activity and prepares the patient for the cold application. Methods: Full dry-pack, full wet-pack, vapor or steam; heat, superheated dry hot air, full bath and incandescent electric-light bath. The last-named is *undoubtedly* the best.

2. A warm application. The warm water cleanses the skin by its mecnanical effect, increases the dilatation of the blood-vessels and prepares the patient for reaction. Methods: warm full bath, rain bath, needle bath,

pharmaceutical houses were examined. A comparison of the potassium iodid claimed to be present in the product of the "physicians' supply houses" with that indicated by an estimation of the iodin content of these tablets showed a range of from 88.6 to 106.6 per cent. of the claimed amount. The products of the five "regular" pharmaceutical houses showed a range of from 99.1 to 101.4 per cent. of the claimed content.

This examination shows that the products of the "pharmaceutical houses" show a markedly smaller variation than those of the "physicians' supply houses." That price had nothing to do with the variation is shown by the fact that the lowest-priced brand is among those which have the highest content of potassium iodid. Table 2 gives the results obtained.

* The potassium iodid content was determined by pulverizing ten tablets, thoroughly mixing the powder and from 0.2 to 0.3 gm. portions of the powder taken and titrated according to the method of Andrews (Jour. Am. Chem. Soc., xxv, 756). The average weight of ten tablets was determined and from this and the potassium iodid content of the material constituting the tablets the potassium iodid content of the average tablet was calculated; the content thus found, compared with the claimed amount of potassium iodid, indicated the percentage of claim found.

FLUIDEXTRACT OF HYDRASTIS (GOLDEN SEAL)

Fourteen specimens from the "physicians' supply houses" were obtained and five from "regular" pharmaceutical houses. The specimens were assayed according to the method of the U. S. Pharmacopeia. The products of the "physicians' supply houses" were found to range from 84 to 135 per cent. of the amount required by the U. S. Pharmacopeia, and the products of the "regular" pharmaceutical houses ranged from 82 to 119.5 per cent. of the U. S. Pharmacopeia standard. While as before the products of the "physicians' supply houses" show a wider variation than the products of the "regular" pharmaceutical houses, the difference in this case is not great. The lowest values of the two classes of firms are practically the same.

Since the assay method for fluidextract of hydrastis has been official for nearly eight years and is most simple, it is rather surprising that a large pharmaceutical firm, supposed to have well-equipped scientific laboratories, should still be unable to approximate more nearly the U. S. Pharmacopeia standard. Table 3 gives the results obtained.

To test the accuracy of the manufacturing methods and the technical training of those responsible for the products sold by the "physicians' supply houses" three pharmaceutical preparations were selected, namely, solution of potassium arsenite, or Fowler's solution, ointment of zinc oxid, or zinc ointment, and fluidextract of digitalis.

SOLUTION OF POTASSIUM ARSENITE (FOWLER'S SOLUTION)

Specimens of solution of potassium arsenite from fourteen "physicians' supply houses" and five "pharmaceutical houses" were examined. A comparison of the arsenic content claimed to be present in the products of the "physicians' supply houses" with that given by the U. S. Pharmacopeia method for the determination of arsenic shows a variation of from 80.4 to 103.9 per cent. The products of the "pharmaceutical houses" showed a variation of from 96.7 to 102.2 per cent.

* This specimen was assayed in triplicate. The results were 1.61, 1.69 and 1.63 gm. hydrastin per hundred c.c. In the last assay after the two prescribed shakings with ether had been made a third and a fourth shaking were carried out and the residues weighed separately. The total increase was but 0.03 gm. of hydrastin per hundred c.c., showing that the extraction as directed by the U. S. P. was practically complete.

† Maximum; ‡ Not declared.

Again the products of the "pharmaceutical houses" vary somewhat less than those of the "physicians' supply houses" and, as was found before, the price does not indicate quality, as the lowest in arsenic content was next to the highest in price. While in ordering these preparations the official title "Solution of Potassium Arsenite" was used, the product sent by Parke, Davis & Co. was labeled "Concentrated Fowler's Solution (without Lavender) for Preparing Fowler's Solution," and was stated to be eight times the strength of the official solution. The preparation sent by Pitman-Myers Company was labeled "Veterinary Solution, Potassium Arsenite P-M Co." Table 4 gives the results obtained.

OXIDE OF ZINC OINTMENT

Oxid of zinc ointment or, as it is commonly known, zinc ointment, like most other ointments, requires some skill to make it. Like most other ointments it is prone to deteriorate and when marketed is likely either to show signs of deterioration—rancidity of the ointment base or separation of the solid material from the fat—or else to have been rendered more permanent by departing from the official formula. The specimens purchased were therefore examined, first to determine whether or not they had been made according to the U. S. P. formula for zinc oxid ointment, and if not, whether or not a proper declaration of the fact was made on the labels. Second, the physical character was noted to determine whether or not the ointments were satisfactory preparations, that is, well-made ointments.

Of the fifteen preparations obtained from the "physicians' supply houses" five were made with the U. S. P. base, while the remaining, by such terms as "special," "improved," etc., were acknowledged to have been made with an unofficial base, generally petrolatum. In the case of the products obtained from the "regular" houses, four were declared to be made with the U. S. P. base. In the case of one specimen, that of Sharp & Dohme, departure from the U. S. P. formula was acknowledged, or at least hinted at by the statement that it was "Strength of Unguentum Zinci Oxidi, U. S. P." This specimen was found to contain, besides the required amount of zinc oxid, about 20 per cent. of corn-starch. As to the physical appearance of the ointment as obtained from the two classes of houses, those from the "regular" pharmaceutical houses were the best, in spite of the fact that the less stable U. S. P. base was present in three specimens out of the five. About five of the others approached these very closely while the remaining five were more or less markedly inferior products, despite the fact that only one-half were made with the U. S. P. base.

The United States Pharmacopeia (VII) assay method for Liquor Potassi Arsenitis was used in making these determinations.

The determination of zinc oxid[4] content denoted some variations from the required 20 per cent. standard; but in no case was the variation sufficient to warrant a charge of adulteration in any specimen.

The examination of zinc oxid ointment clearly points to the need of extemporaneous preparation by the retail pharmacist of preparations of this sort which are prone to deteriorate with age, particularly when exposed to changes in temperature such as are most likely to occur during transportation from the manufacturer to the jobber, the druggist or the physician.

FLUIDEXTRACT OF DIGITALIS

In view of the publicity which has been given the variability of digitalis preparations and because it is well known that a fluidextract of digitalis representing the

The average of the preparations of the "physicians' supply houses" is 197 mg. per kilogram of cat.

The average of the preparations of the "regular' pharmaceutical houses is 136 mg. per kilogram of cat.

Four c.c. of each of Nos. 1, 2, 3, 7, 8, 10, 11, 12, 14, 16, 17, 19 and 20 were taken, mixed and diluted with 5 per cent. alcohol and enough normal salt solution to make each cubic centimeter represent 20 mg., and this was tested on cats in the same way. The results of three tests were 187, 156 and 241 mg., an average of 195 mg. per kilogram.

* The figures in this column show the milligrams of drug represented by the volume of the preparation taken required for 1 kg. cat to produce death.

† The figures in this column were obtained by calculation from the values "Mg. Drug per Kg. Cat," taking the strongest preparation as 100.

‡ Tincture.

---

[4] While, with the exception of the Sharp & Dohme product, the non-fatty constituent in each case was found to be only zinc oxid, the estimations of the zinc content were unsatisfactory. Two methods were employed: (a) direct ignition and weighing of the residual zinc oxid, and (b) extraction of an ether solution of the ointment with dilute hydrochloric acid, evaporation of the acid precipitation of the zinc as basic zinc carbonate and ignition to zinc oxid. The results obtained by these methods, while permitting conclusions of variability given above, are not entirely free from error and hence are not reported.

full strength of the drug is difficult to prepare, this examination was made to include fluidextract of digitalis. The results of an examination promised to be the more interesting because the firms which supply the drug trade have laid much stress on the quality of their products, which are claimed to be physiologically assayed. The smaller houses, on the other hand, unless they purchase their supply elsewhere, may be assumed not to standardize their digitalis preparations. Accordingly fluidextract of digitalis was ordered from the "physicians' supply houses" included in the list and also from four pharmaceutical firms. While all of these firms agreed to furnish fluidextract of digitalis, and while in each case fluidextract of digitalis was the item set down in the invoice, in two cases the preparations sent were labeled "Tincture Digitalis, U. S. P." While they were examined and are included in the list, it should be borne in mind that a reliable tincture is more easily made.

The examination of the digitalis preparations was made in the Loomis laboratory of Cornell University, under the direction of Dr. R. A. Hatcher, the "cat method" of Hatcher being used for the tests. Table 5 gives the results obtained.

The demonstrations represented in Table 5 were made with the understanding that exactness was not necessary, it being desired to know whether or not the specimens represented a good quality of digitalis. When such enormous variations in activity are dealt with as are shown between the several specimens it matters little whether or not a very exact figure for any one preparation is determined, and hence the results reported are sufficiently exact.

The table confirms the generally held belief that commercial digitalis preparations vary most widely, for it is seen that the H. K. Mulford preparation, the most active, is four times as active as the weakest, that of the Ray Chemical Company. Even the four preparations of the pharmaceutical firms, which may be assumed to have been checked by physiologic assay, show a variation of more than 100 per cent. in strength. The activity of these specimens is such that only the fluidextract of the Columbus Pharmacal Company and of the H. K. Mulford Company fully represent a digitalis of good quality.

While the products of the four "regular" pharmaceutical houses (Eli Lilly & Co., H. K. Mulford Company, Parke, Davis & Co., and Sharp & Dohme) show a wide variation, the product of Eli Lilly & Co. having only 42 per cent. of the strength of the Mulford preparation, the products of the "physicians' supply houses" show a lower and still wider range of strength. Here the strongest fluidextract has a strength of 65 per cent. of the Mulford product, while the lowest has a strength of but 29 per cent. Since there is no official standard for digitalis preparations, and in view of the fact that the physiologic methods employed by pharmaceutical houses are in general claimed only to guarantee uniformity for the product of a particular firm, no sharp conclusion can be drawn from this investigation. It does show, however, that in general the products of the "physicians' supply houses" are less active than those obtained from the pharmaceutical firms.

CONCLUSIONS

Although the examinations reported in the preceding do not cover a wide field, they are sufficient to show that the random charge of sophistication and adulteration which has been repeatedly made against "physicians' supply houses" is unjustified. It shows, on the contrary, that, as has been argued before, standard drugs are likely to be of fair quality. On the other hand, the examination does show that the products put out by this class of firms, *without* being sold at a materially lower price, are less reliable as regards uniformity than those of the pharmaceutical houses. In other words, while "physicians' supply houses" do not deliberately adulterate or sophisticate their standard drugs, their products are evidently produced by those who are less competent and less skilled than are those of the "regular" pharmaceutical houses.

A discussion of the products of pharmaceutical houses would be incomplete without reference to what appears to be the highest aspiration of pharmaceutical manufacturers, namely: a long list of "specialties" and "elegant pharmaceuticals." When one compares this class of preparations as put out by the two classes of firms one is struck with the fact that the specialties of the "physicians' supply houses" are a little more unscientific, a little more devised to mislead or cheat the user, are a little more brazen in their imitation of fraudulent and worthless proprietaries and more deliberately aimed to satisfy the unthinking physicians than are those of the "regular" pharmaceutical manufacturers.

While the specialties of the "physicians' supply houses" do not differ radically from the specialties sold by the "regular" pharmaceutical houses, their use is more likely to be uncritical. For this reason they are a constant invitation to the dispensing doctor to shirk the expenses of keeping in stock and the labor of selecting the medicines which his patient should have, and instead to treat all diseases with a few of the "shotgun" prescriptions which he may have bought.

535 North Dearborn Street.

ABSTRACT OF DISCUSSION

DR. B. FANTUS, Chicago: The report of Professor Puckner shows how valuable the work of the Council on Chemistry and Pharmacy is. It seems to be maid-of-all work. It shows, too, how absolutely fair the Council is in its reports. As there is a danger, perhaps, that this assembly might be taken to be in favor of dispensing by physicians, I offer the following resolutions for your consideration:

WHEREAS, Dispensing by physicians is liable to lead to inadequate medication by restricting the practitioner to a generally very limited stock of drugs; and

WHEREAS, The physician, unless he be also a pharmacist, is not qualified by training or experience to judge of the purity and strength of the drugs he dispenses, or to take care of their proper preservation, or to prepare them for that form of administration most suitable for the patient's needs, making individualization in treatment impossible; and

WHEREAS, The public is insufficiently safeguarded against dangerous and even fatal mistakes, when only one mind and hand stands between the poison and the patient, therefore be it

Resolved, That the American Medical Association advise its members against dispensing, excepting in cases of emergency or when the services of a properly qualified pharmacist are not available.

DR. RAY L. WILBUR, San Francisco: We could not as a section put ourselves on public record as favoring this resolution. We could only recommend it to the House of Delegates for their action.

DR. M. I. WILBERT, Washington, D. C.: Substantially the same suggestion as Dr. Fantus proposes is made in the Code of Ethics adopted by the American Medical Association at Atlantic City last year and embodied in the "Principles of Medical Ethics."

DR. RALPH ST. J. PERRY, Farmington, Minn.: In order to aid discussion I second the motion.

Dr. Alexander S. von Mansfelde, Ashland, Neb.: I am sorry the gentleman seconded the motion. We know how very little we know; let us not publish the fact to the world at large. I warn the gentleman that unless he withdraws his second I will move the laying of that motion on the table, because it is injudicious.

Dr. Ralph St. J. Perry, Farmington, Minn.: I am glad that I seconded that motion; otherwise we should not have had that open confession. I withdraw my second. This subject has been discussed in *The Western Druggist* and *N. A. R. D. Notes;* the journals have been rampant on the question of double standards of the drugs put up by the manufacturing pharmacists, asserting that they put up one grade to supply the dispensing doctor and another to supply the pharmacist. When I go to the editor and say, "I am a dispensing doctor and I want to know the manufacturer who puts up two grades, one for the dispensing doctor, an inferior grade, and another for the pharmacist, a superior grade; tell me which one of the manufacturing firms puts out the poor quality of drugs for the physician and which puts out the standard stock for the druggist," not one of them will give names. Professor Remington and others of the older members will recall that that same question relating to quinin pills was raised years ago. The societies and journals were burdened with papers detailing the differences in strength in various quinin pills and these shortages were represented by giving figures for the firms manufacturing the pills. There was not one analyst who had backbone enough to give the names of the firms. Professor Puckner has shown in The Journal that certain drug-houses are manufacturing drugs which are not up to the proper strength. Now when Professor Puckner publishes these statements we should like to have him name the man. He gave two or three instances in which the drugs ran below the standard. He did not say whether that was a sporadic or a chronic accident. Was more than one test of the same product made? I want to know whether the low standard was an occasional or a constant condition.

Dr. F. J. Wulling, Minneapolis: This question of inferiority of tablets and pills is as old as the hills. The question that we should concern ourselves with is: Are things getting better or are they at a standstill? Are drugs of to-day more reliable, more efficient than they were ten or twenty years ago? If so, conditions are getting better; if not, something should be done, and a body like this should see that standards are laid down and then observed. Has Professor Puckner noticed improvements?

Prof. W. A. Puckner, Chicago: I have given only an abstract of the work, and when the entire report is published the source of each drug examined will be given. Whether or not the variation is sporadic I am unable to say at this time. The work was taken up because of the insistence on the pharmaceutical press during the last year of the utter worthlessness of the drugs supplied to physicians by supply houses. The examination was based on a single specimen bought from the firm. It may have been an accident. The particular case of fluid hydrastis surprised me as being below standard, inasmuch as it was the product of a manufacturing house that is generally believed to stand high. I was informed by Professor Clark of the Illinois School of Pharmacy that he also had examined a specimen and found it of distinctly inferior quality. It is quite likely that he obtained a sample from the same barrel my sample came from. I believe that the reports from the chemical laboratory have done something in the direction of improvement. It is to the credit of no firm to be found wanting and it will, no doubt, cost a firm a good deal in loss of prestige to have its products found inferior. I believe that no firm has deliberately adulterated. The amount of money to be gained in that way is insufficient. Standard drugs have improved decidedly. On the other hand, some work done in the laboratory with complex mixtures—things which were utterly worthless anyhow—has been published of late, including a third examination of a certain tablet, the investigation covering three years. These firms have done practically nothing to improve their products, evidently thinking that any physician who is fool enough to prescribe such mixtures does not deserve to get good drugs. The same I think can safely be said also of the worthless drugs supplied to the physician who prescribes them. He is not competent to know the difference and he does not care, and the pharmacist does not care either. I think that the high-grade drugs have improved decidedly.

SYPHILIS AND THE NERVOUS SYSTEM*

JOSEPH COLLINS, M.D.
Physician to the Neurological Institute of New York
NEW YORK

If all that has been written on the subject of syphilis were collected and made readily accessible a lifetime would probably be too short in which to peruse it. What excuse have I then for adding to it? Have I something to say that will add to the sum total of our knowledge of it, and which shared with you will combat the disease more successfully? I have definite views concerning the treatment of syphilis based on a very large experience with the important clinical display of syphilis, that of the nervous system, which are not generally accepted, but which should be accepted that syphilis may be successfully treated. I do not mean to say that these views are original, for I know that they are taught by many progressive syphilologists. They are not held by the rank and file of the profession, however, if I may judge from an extensive contact with them.

The treatment of syphilis has entered a new era; first, because we have a test for its detection and, second, because we have had added to our means of combating it a curative agency that equals and probably exceeds mercury. Although skeletal and visceral syphilis are not so flagrant in their display as they were a hundred or even fifty years ago, because of the universal conformity to most of the laws of hygiene, syphilis is still a scourge and a pestilence, a menace to the health and efficiency of every nation.

Fortunately we need not concern ourselves with the origin of syphilis. Each European nation accused the other in turn of carrying the disease to its shores and all accused America. What we really know about it is that Girolamo Fracastorio (1483-1553), a Veronese physician and poet, gave it the name and described its origin, course and treatment in hexameter verse. The hero of the poem, a shepherd, Syphilus by name, in the employ of King Alcithous, has blasphemed the Sun and this deity in a moment of wrath strikes him with the disease of which Venus has had a monopoly in modern times:

> A Shepherd once (distrust not ancient Fame)
> Possessed these Downs and Syphilus his Name,
> A thousand heifers in these Vales he fed,
> A thousand Ewes to those fair Rivers led.

He is cured of the disease by the nymph Americi (America) who administers guaiacum. This poem, which deserves to be read even to-day, is apparently well-nigh forgotten save by a few litterateurs and physicians. A translation of it is to be found in the third part of Dryden's "Miscellany." The poem seems indeed to have been widely read and to have been given serious consideration. The worst that can be said of it, comments Professor Saintsbury, is that it could have been done much better in prose a criticism that may be made with even greater justice of much modern English poetry—"The Widow in the Bye Street," for instance.

---

* The oration in medicine before the Illinois State Medical Society held in Peoria, Ill., May 22, 1913.

The disease presented itself to Fracastorio and his contemporaries as a terrible epidemic quite independent of its occurrence from individual misconduct. It is for this reason that he and his literary successors were able to treat it in an impersonal way much as they might treat small-pox or scarlatina. No odium of profound and disgusting personal immorality attached to its possession such as is attached to it to-day.

When it began to be realized that syphilis was a disease that had its origin in sin and its cause in what we are pleased to call immorality, then it became a tabooed subject. No newspaper dared print the word, it was never heard save in medical discussion, and even daring social workers in the field of hygiene usually felt obliged to speak of it as lues, which only the more sophisticated of their auditors understood at once, or, if they desired to be still more refined, as the Fracastorian malady. Two years ago Harvard University announced a series of twenty lectures to be delivered in "popular" style for the edification and benefit of the public. Among them was one on syphilis. It is said that no newspaper in the town which the Brahmins love to have called the Athens of America dared print the name of the most unmentionable of all subjects. Now all this is changed and Brieux, a litterateur long without honor in his own country, though now a member of the French Academy, did it. He wrote a dramatic piece called *Les Avariés*—"Damaged Goods." Before the play begins the manager appears on the stage and says, "Ladies and Gentlemen: I beg leave to inform you that the object of this play is a study of syphilis in its bearing on marriage." Then the actors and actresses proceed to give the most meticulous account of its diagnosis, the culpability of the husband, the infection of the wife, the transmission to the infant, the inoculation of the wet-nurse and so on. This play ran in New York for two months or more a short time ago, and I have heard temperate, conventional individuals say that they thought it should be given at Vassar, at Smith and at Bryn Mawr colleges. Be that as it may, the taboo has been removed, and, although we probably shall not hear syphilis discussed at the dinner table, as we do most human ills, and with avidity if they happen to be surgical, there is no doubt that it will be considered good form to instruct the laity, plainly and openly, concerning the disease and its capacity to bring incomparable misery to its victims.

But in addition to instruction of the laity, our medical students must be properly instructed. It is safe to say that in no medical college or university of this country is the subject of syphilis properly or adequately taught. In every instance it is included under the caption of dermatology or genito-urinary diseases. It has comparatively small relationship to the former and practically none to the latter. The subject of syphilis properly taught must be done by the general clinician and internist who may also be dermatologist, neurologist or even ophthalmologist, but he will never grasp the problem of syphilis unless he knows it as it affects all the organs and tissues of the body.

Syphilis is a disease due to the infection of the body by a thin, spiral organism called *Spirochaeta pallida*, whose cycle of development has not yet been satisfactorily established. Very little indeed is known of its life history. It may or may not produce what is called a characteristic lesion at the point of inoculation, namely, the Hunterian chancre. Certain it is that many physicians still believe that it is necessary that a chancre with indurated base and other so-called characteristic features must exist if the individual becomes inoculated with syphilis. This is a pernicious belief. Inoculation with syphilis need not and often does not cause a "characteristic" lesion. It is well known that a certain time elapses between inoculation and systemic infection, a variable one. When it enters the vessels and the lymphatics its choice is apparently the walls of the lymphatics, from which it enters the intercellular spaces of the tissues. It is found especially with mononuclear infiltration, and Metchnikoff believes that it exerts a chemotactic influence on those cells.

The prevention of syphilis is in reality one of the most urgent and important problems, from a hygienic and economic point of view, that the physician can set himself. It is a subject to which many earnest men and women are devoting their energy. Their efforts must be barren until the light of popular education or of enlightenment bathes the subject. This aspect of the subject cannot be considered here. It is the syphilitic diseases of the nervous system to which I invite attention. *There are diseases of the brain and spinal cord, their coverings, linings and blood-vessels that are caused solely by syphilis.* They constitute the bulk of all organic nervous diseases. These diseases are tabes, paresis, certain forms of myelitis and softening of the brain and spinal cord, meningitis, endarteritis and gummatous formation constituting tumor. Each of them, it matters not what the seat or extent of the morbid process, causes symptoms which taken together constitute well-defined clinical entities, and as such may be diagnosticated with readiness and certainty. Many other disorders of the nervous system and especially functional ones, neurasthenia, headache, states of unattributable depression have, since the introduction of a positive test for the existence of syphilis, been shown to be dependent on this infection.

Not so many years ago it was taught that involvement of the nervous system was a late manifestation of syphilis. Now we know that this is not so. I shall not detain you with statistics to uphold these statements but they have been published by myself and many others. Nervous diseases, to be sure, do not occur during what is often called the florid stage of syphilis, that is, during the time that the mucous membrane and cutaneous manifestations usually occur. It is during this period however that the parasite invades the lymph-spaces and channels of the nervous system and begins the warfare which for years may be so silent and its conduct so insidious that the victim remains unconscious of it. The most serious of the organic diseases of the nervous system, encephalitis, myelitis, cerebral and spinal endarteritis, may occur during the first months of the syphilitic infection, and diseases such as tabes and general paresis, which are exclusively syphilitic in their causation, may and often do display their initial symptom within five years after the date of infection. If you turn to your text-books and encyclopedias of medicine you will find that tabes and general paresis are referred to as parasyphilitic or metasyphilitic diseases, and nearly every author will discuss the probability that there is some other cause than syphilis for these diseases. But the day of such designation has passed. Tabes and general paresis are syphilitic diseases and the dictum that syphilis produces a "characteristic" inflammatory reaction, namely, the granuloma must be given up. Before we had a reliable test for syphilis and before we had given a specific valuation to the information obtained from study of cerebrospinal fluid, we were obliged to use such terms as parasyphilis (which means pertaining in an indirect or remote way to syphilis) or metasyphilis (transformed from syphilis) because all pathologists were agreed that the syphilitic pathologic change is a characteristic one. The lesion of tabes and of general paresis is as far removed from the "characteristic" as can possibly be and now that Noguchi and Moore have demonstrated the existence of the *Spirochaeta pallida* in the lesion of general paresis it will have to be admitted that such lesion is syphilitic. Indeed, the conception of parasyphilitic disease and metasyphilitic disease, namely, that the syphilitic virus underwent some transformation before it caused the tabes or general paresis, has been a menace to the successful treatment of these diseases, for how could one justify himself in giving antisyphilitic treatment if the *de facto* determining cause was not the syphilitic poison acting as such? I believe that nothing has done so much to stultify our efforts in the treatment of syphilis and syphilitic organic nervous diseases as the sort of rule of thumb which called for the giving of mercury in the second stage, potassium iodid in the third. For the most common of all diseases that flow out of syphilis, organic nervous diseases were considered to be tertiary manifestations of the disease and were therefore often never given a real antisyphilitic. It will advance the treatment of syphilitic diseases of the nervous system if we now and for all time give up the designations "parasyphilitic," "metasyphilitic," "tertiary syphilis" and the like. Syphilis is syphilis just as indisputably as a good cigar is a smoke, and it matters not when or under what veil it is encountered.

The measures that permit us to say thus positively that syphilis is syphilis at all times are popularly known as the Wassermann test of the serum of the blood, of the cerebrospinal fluid and its various modifications (the so-called Stern's method, Hecht's method, Noguchi's method) and the cytologic examination of the cerebrospinal fluid. The Wassermann reaction has been described many times since the discovery of the Bordet-Gengou phenomenon in 1901 on which it is based. Without entering here into a discussion of the nature of the reaction, it must be granted that clinically the test with but very few exceptions is pathognomonic of syphilis. It is highly probable that the reaction is not strictly specific, that the substance produced in the infected individual is not a true antibody, and that the so-called antigen is not a true antigen.

The specificity of the reaction is a most important matter. That a positive reaction follows in conditions other than syphilis is certain, but aside from such diseases as yaws, leprosy and trypanosomiasis, a positive Wassermann reaction is rarely obtained. Hoehne found a positive reaction but twice in the examination of 1,100 serums taken from healthy persons or from persons suffering with other diseases than syphilis and in neither of these two could syphilis be excluded. McDonagh, Mueller and Morawitz in reporting on 5,000 cases did not obtain a single positive result in any case from which syphilis could be excluded.

Since the opening of the Neurological Institute in New York, a hospital devoted exclusively to the study and treatment of nervous and mental diseases, the Wassermann reaction has been done by Dr. D. M. Kaplan, director of the clinical laboratory, upward of 10,000 times. Of these 10,000 analyses undertaken in the great variety of diseases that come to a hospital for nervous diseases, a considerable proportion of which are metabolic and visceral, about 28 per cent. have shown a positive Wassermann reaction. In practically all of these the Wassermann reaction of the serum and the evidences of syphilis in the cerebrospinal fluid were corroborative of the clinical findings. In view of the complexity of the reaction we never felt justified in pronouncing a case one of syphilis unless we had clinical corroboration.

The cerebrospinal fluid, which is secreted to the amount of about 150 c.c. a day by the chorioid fringes, is a pale, colorless liquid containing no cellular element except a few large endothelial cells and an occasional lymphocyte. On being heated, it becomes slightly clouded; this is due to a proteid called globulin. Traces of dextrose are found. Study of this fluid taken from patients suffering from organic disease of the nervous system, and especially from those that flow out of syphilis, shows that this fluid is altered in a way that is highly characteristic, indeed almost pathognomonic and which may be utilized for diagnostication.

In the first place, in all syphilitic diseases of the central nervous system the reaction of the cerebrospinal fluid to the Wassermann test is plus in the vast majority of instances, unless the disease has been influenced by treatment. It need not be plus, however, for a negative Wassermann reaction of this fluid does not necessarily speak against the existence of any of these diseases, especially if the cell-content, the proteid or the glucose is in excess. In all syphilitic diseases of the central nervous system the lymphocytes are increased to a variable extent from ten to a thousand or more to each cubic millimeter. The mononuclear elements predominate. The globulin is increased, the dextrose, which is normally present, may in very acute meningeal irritations be absent. From an examination of over 3,000 cerebrospinal fluids, Dr. Kaplan and myself have come to conclude that the formulary of Table 1 expresses approximately the alteration in the serum and in the fluid in tabes, general paresis and cerebrospinal syphilis:

TABLE 1.—SERUM AND FLUID ALTERATIONS

	Blood Wassermann	Cerebrospinal Fluid Wassermann	Cells	Globulin Excess	Fehling's Reduction
Tabes	+ as a rule; occasionally —.	+ or —	numerous 20-100 or more	+ or —	+
General paresis.	+ ; rarely —	+	few 5-30	+	+
Cerebrospinal syphilis.	+	+	large number 100-1500	+	+

The treatment of syphilis by the rank and file of the profession of the present day consists in the administration of mercury by the mouth, usually in the form of the protiodid, kept up for a year, followed by the administration of mercury and iodid mixed in solution and kept up for another year, followed finally by the administration of potassium iodid alone in doses ranging from 10 to 60 grains or possibly even more, depending on whether or not there are any so-called "evidences" of syphilis. The patient then maintaining that he feels well or fairly well and having no outward manifestations of the disease is told that he is cured, that he may marry and procreate and that the disease is a thing of the past. I do not intend to say that there are not hundreds of patients afflicted with syphilis who are being treated otherwise than in this way. Unquestionably in every considerable city of the country and probably in many towns the diagnosis of syphilis is being made by the detection of the spirochetes, the infection of the blood is determined by the Wassermann reaction, and mercury and salvarsan are being given appropriately and the results of their action determined not alone by the disappearance of the clinical evidence of the disease but by a cessation of a positive Wassermann reaction in the serum of the blood. But I believe that for one case dealt with in this fashion, there are a score that are dealt with in the former fashion.

Now, this statement requires a discussion of five topics:

1. Is syphilis ever a local disease and is its only locus a true or Hunterian chancre?
2. Is the administration of mercury by the mouth a competent way of getting sufficient mercury into the system to kill the spirochetes in their *lymphatic invasion?*
3. Is potassium iodid in any way, shape or form a spirochetacide and therefore a true antisyphilitic agency?
4. What is the clinical value of the Wassermann reaction?
5. Is salvarsan or neosalvarsan an antisyphilitic remedy comparable in its efficiency with or greater than mercury?

My reply to the first question must be an expression of individual belief reflecting the opinion of such a competent authority as Fordyce. Unquestionably a variable period elapses between the time of inoculation and the time when the clinical evidences of syphilis display themselves in any of the tissues of the body. Likewise the Wassermann reaction of the serum of the blood is not positive in individuals infected with syphilis until after a period of from days to weeks following the infection. At one time it was the accepted teaching that during this period no constitutional treatment looking to the destruction of the syphilitic virus should be administered. Regrettably there is much teaching of this kind even to-day. Indeed, until recently it has been taught and to-day it is very widely believed that the syphilitic infection has its point of entrance only in the Hunterian chancre; that the chancroid and the herpes patch and the abrasion are never the point of entrance of the spirochetes. It has been amply demonstrated by inoculation experiments in animals that the system may be infected by the spirochetes without producing a so-called typical induration; and there is abundant, convincing evidence to show that the site of the inoculation in many instances in man displays only a "non-typical" ulceration. The fact that there is neither clinical nor serologic detectable evidence of infection does not means that such infection does not exist. There is a period of incubation in every infectious and protozoal disease. During this period of incubation the vital resistance of the protective tissues of the body is being overcome. Often, however, the evidences of infection are not to be found during this period in the tissues nor do they display themselves clinically; it still does not follow that the infection does not exist. It is not unlikely that one of the most important steps in our progress in treating syphilis adequately is to apply the spirochetacide, salvarsan or mercury, during this period of the disease. Success is much more likely to attend an attempt at destruction of the enemy's army if it is vigorously and overwhelmingly attacked during transportation and mobilization than if such action is delayed until it is securely mobilized and entrenched.

The reply to the second question that we have put to ourselves is not an easy one. Individually, I can answer it readily and to myself satisfactorily: The administration of mercury by the mouth is not an adequate and satisfactory way of administering the remedy. My opinion, however, may be biased by my experience, especially by my experience as a neurologist. Practically all the patients that I have seen with diseases having their origin in syphilis have been thus treated, and such experience gives me a conscious and unconscious prejudice against such mode of medication. Indeed, some years ago I published very considerable statistics which seemed to show that persons who had syphilis and who had been treated for it in the orthodox way (that is the way described above) developed nervous diseases that flow out of syphilis as soon after infection and as severely as those who had little or no treatment. This could be interpreted only as meaning that the orthodox treatment was as little efficacious in preventing certain syphilitic diseases as no medication at all. And this is my belief at the present time.

In opposition to this many will cite their own experience, which is that they have treated scores of cases of syphilis in the orthodox way and the patient has remained cured. Such antagonists will have greater difficulty, however, in maintaining their position than I. In the first place, once they know, and knowing believe, that the vast majority of organic affections of the central nervous system and its coverings are syphilitic diseases and that a very much greater proportion of cardiovascular diseases are syphilitic than were formerly believed to be, their verdict is contrary to the evidence. In the second place, unless they are in a position to know what has become of their syphilitic patients ten, twenty and thirty years after they have been under treatment, and of their descendants, their experience does not entitle them to give testimony. There can be no doubt that many cases of syphilis, possibly the majority, terminate in complete recovery while under such medication, but this cannot be construed as proof that the treatment cures the disease. It is more probable that the combative power of the protective tissues of the body is sufficient to overcome syphilis without aid in many instances. Moreover, there is always a tendency, in syphilis which has been treated, for the symptoms to disappear spontaneously, only to recur later. It is more than likely that there are definite strains or varieties of the *Spirochaeta pallida,* that there may be one strain that has a predilection for lodging in the lymph-spaces and channels of the central nervous system and another that has a sort of chemotaxis for the vascular system and for the skin. We have no means of proving at the present time that this is so, but it can scarcely be a coincidence that so many of the patients that come to me with syphilitic nervous diseases have been told by the physicians who treated them that they had very light attacks. One may have a light attack of diphtheria or of typhoid and be the legitimate recipient of congratulations but to have a light attack of syphilis is comparable to having an introduction to the executioner a month or a year before being guillotined.

It would be interesting and extremely useful to know what proportion of syphilitics develop nervous diseases, but so far no statistics on this subject have been at all convincing. If we can devise some system for reporting syphilitic diseases in the way diphtheria is now reported, without betraying the identity of the sufferer, we shall be in a position to get such statistics within another generation; by that time it is to be devoutly hoped that syphilis will practically be conquered.

In a paper read before the New York State Medical Society in 1910,[1] I made the statement that there was little evidence to show that potassium iodid was a real antisyphilitic agency. So far as my knowledge goes no evidence has since then been adduced. Despite this it is no exaggeration to say that tons of potassium iodid are administered every year to patients suffering from syphilis. I may say without any exaggeration whatever that scarcely a patient comes to me, either in my private practice or in my service at the Neurological Institute, bearing a letter from his physician requesting counsel as to the nature and treatment of the patient's ailment, in which it is not set forth that the patient has been taking potassium iodid in varying doses of from twenty to several hundred grains often for a protracted time. We have not given an ounce of potassium iodid in the three and a half years that the Neurological Institute has been in existence. During that time I have personally seen, studied and treated upward of six thousand patients, many of them victims of advanced nervous disease, many of them victims of serious nervous diseases having their origin in syphilis. No attitude could be more divergent. Either there must be tangible proof that potassium iodid is useful in the treatment of syphilis *per se* or my position must be right. I do not deny that potassium iodid is an extremely useful agency in dissipating, disintegrating and absorbing certain pathologic tissues which are the result of the activity of the syphilitic virus. I likewise readily admit that in the treatment of the granulomas of late syphilis the iodids are of the greatest value in restoring patency to blood-vessels occluded by tissue which results from the activity of the syphilitic virus so that the active spirochetacide can reach the real disease and its cause.

In a peculiarly distressing book, recently published, entitled "The Private Life of Henry Maitland," in reality a meticulous statement of the moral infirmities of George Gissing, which justifies the saying "God save us from our friends," Morley Roberts, the shameless perpetrator of the work, in a desire for self-glorification, quotes a letter from Gissing to his physician:

> You remember that patch of skin disease on my forehead? Nothing would touch it; it had lasted for more than two years, and was steadily extending itself. At last a fortnight ago I was advised to try iodid of potassium. Result—perfect cure after week's treatment!

This is the sort of thing that potassium iodid does for the manifestations of syphilis, but it leaves the disease itself untouched.

Reduced to a few words my protest is against the use of potassium iodid as a routine measure in the treatment of syphilis, and particularly against reliance on it to check the activity of the *Spirochaeta pallida.* To hold that potassium iodid, because of this, is an antisyphilitic agency, seems an absurdity. An ant raises up an anthill and a mole causes a deformity of your lawn but, if these are leveled off you are likely to forget that the ant or the mole may still be at work underground.

THE CLINICAL AND THERAPEUTIC VALUE OF THE WASSERMANN REACTION

I assume that it is generally admitted that the Wassermann reaction alone of the blood-serum of an individual who has had syphilis is sufficient evidence of active infection to justify antisyphilitic treatment, even though no clinical evidences of syphilis exist. This reaction in the blood-serum and in the cerebrospinal fluid is quite sufficient to justify such treatment when disease of the nervous system is suspected, especially if there is a lymphocytosis of the cerebrospinal fluid, even though there is no definite symptom of nervous disease. On the other hand a negative reaction does not mean that syphilis has not been or is not the cause of the symptoms or disease that is being investigated. During the latent period of syphilis, that is, the period in which there is an equilibrium between the host and the parasite, the reaction is often negative, perhaps as often as 50 per cent. of the cause. This equilibrium may cease to exist any day; then the negative reaction will become positive. This was one of our most enigmatic experiences when we first began investigating the serology of nervous diseases. A succession of negative reactions must be obtained before syphilis can be excluded as the cause of any nervous disease. A single negative reaction means nothing. Moreover, a negative Wassermann reaction frequently becomes positive after one or two injections of salvarsan. The salvarsan has a precipitating or provocative effect, so to speak, on the reaction. It is supposed to be caused by the setting free of the endotoxins contained in the bodies of the spirochetes which have been destroyed by treatment or by other causes. It must never be forgotten, nor should we lose the opportunity to recall it to ourselves, that in certain ancient infections apparently no amount of salvarsan or mercury will bring about a condition in which the blood-serum gives constantly a negative reaction. This is the rift in the lute.

IS SALVARSAN OR NEOSALVARSAN AN ANTISYPHILITIC AGENCY COMPARABLE IN ITS EFFICIENCY TO MERCURY?

In attempting to answer question five of our series, it is assumed that mercury is a competent agency to overcome syphilis. Confronted with such an assumption, the question as to why the discovery of salvarsan and the claims made for its efficacy, were hailed with such delight, becomes pertinent. The reason is that it is impossible in many cases, and probably always difficult, to administer a sufficient amount of mercury to cure the disease. The plan of its administration taxes the victim's patience and the resourcefulness of the physician. Administered in the most efficacious way, by inunctions, it is profoundly offensive, to say the least. Administered in the next most efficacious way, that is, intramuscularly, it is frequently painful and occasionally accompanied by disagreeable consequences. Administered by the mouth it is unreliable and tedious. Finally, it matters not in what way it is administered, it is difficult in many instances, perhaps indeed in most, if we consider the fact that many of the victims of syphilis are not only youthful but constitutionally disinclined to take responsibility, to induce the patient to remain a sufficient length of time under treatment to effect cure of the disease. When, therefore, there came from a person and an institution of authority in 1910, the announcement that a remedy then called "606," now called salvarsan and neosalvarsan, a cure for syphilis had been discovered, a cure that would accomplish these results in a brief space of time, there was profound satisfaction throughout the civilized world. In the three years that have elapsed since the remedy has been generally used an enormous literature has been published for and against it. I shall make no attempt whatever to review this literature; first, because I am convinced that the time has not yet come to do so, and, in the second place, because for the results of *individual* experience carefully tabulated, criterions are still sadly wanting. *It is not sufficient*, in order that the therapeutic use of salvarsan may be established, to report only the scores of cases that have apparently been cured. It matters not what the syphilitic disease may be.

---

[1] Collins, Joseph: Syphilitic Diseases of the Nervous System; Their Relationship to Inadequate and Improper Treatment of Syphilis.—The Journal A. M. A., April 23, 1910, p. 1349.

I began the use of salvarsan at the Neurological Institute in June, 1910, therefore have been using it about three years. During that time I have given it to upward of 250 patients suffering with syphilitic nervous disease. A report of 75 of these cases was published[2] and an estimate was then attempted of its value in syphilitic nervous disease. In that paper it was stated "that salvarsan had not replaced mercury, perhaps it never will. To-day these two agencies are used side by side, one often supplementary to the other. The therapeutic potentialities of salvarsan, however, are not yet fully shown. We are convinced that in the treatment of diseases of the nerves that flow out of syphilis, far better results attend the use of salvarsan than of mercury. Our added experience of the past year justifies us in repeating that statement. In order to show the results of treatment in syphilis of the nervous system, I have selected the last twenty-five cases of tabes and have tabulated the results in Table 2.

TABLE 2.—TABES DORSALIS

HOW SHALL SALVARSAN BE ADMINISTERED IN SYPHILITIC NERVOUS DISEASES?

Nothing could be more inimical to the establishment of the real worth of salvarsan than the impression or belief that was widely disseminated in the first months of its use that one or two or three doses of salvarsan cured syphilis. It is possible indeed that such administration may cure some cases of syphilis, but it is possible, indeed certain, that syphilis is a *self-eliminating* disease in many instances. Once the spirochetes have become entrenched in whatever part of the viscera they find warmest reception, from whence they cause structural disease, then it requires repeated doses of salvarsan to cure, if salvarsan cures at all. The longer we use it the more we become conversant with its therapeutic capabilities, the more convinced we are that the dose of salvarsan must be repeated, not once or twice or three times but perhaps twelve or twenty times, and that its action or its effect must be supplemented by the use of mercury.

The plan of treatment which we adopt at present is to administer four doses of neosalvarsan (to men 0.9 and to women 0.5 gm.) intravenously every fourth or fifth day for four doses. At the end of this time examination is made of their blood and cerebrospinal fluid. If a profound impression has been made on these tissues an interval of a month is allowed to elapse without further treatment. If it has not, the patient is put on large and increasing doses of mercury administered in one of two forms, either the salicylate from one-half to two-grain doses suspended in benzoinal and given intramuscularly, or the mercuric bichlorid from one-eighth to one-half grain combined with cocain and given intramuscularly every day or every second day; depending on effects. After the patient has been under such mercurial treatment for a period varying from three to four weeks, the laboratory examinations are repeated. We then determine from a consideration of the objective features of the disease, from the statement of the patient and from the laboratory findings, when the salvarsan shall be repeated. Usually the series is repeated within three months. This plan of treatment is adhered to till the evidences of syphilis in the serum and cerebrospinal fluid disappear.

It is my belief now as it has been formerly that such remote evidence of destruction of certain pathways in the central nervous system as the Argyll Robertson pupil, and the abolition of the tendon-jerks, do not disappear even though the disease be arrested, which it frequently is, unquestionably.

DANGER ATTENDING THE ADMINISTRATION OF SALVARSAN

The dangers of salvarsan administration have been exaggerated. In nearly 1,000 administrations we have seen serious consequences follow the use of the remedy in one instance only. The patient, a young woman who complained of weakness, nervousness and general inability to work and whose blood-serum was strongly positive, developed a few hours after 0.6 injection of salvarsan intravenously the symptoms of transverse myelitis. She recovered completely in four months. The lesion in that instance was probably of the nature of an edema of the cord rather than inflammation. Severe toxic effects of the drug we have seen in four instances. They are those characteristic of acute arsenical poisoning. In only one of these were the symptoms so acute as to give rise to apprehension. They were readily controlled by the free administration of magnesium carbonate and by the use of colon irrigation and hot baths. I have had no cases of blindness which at one time it was freely said salvarsan was likely to cause. Nor have I seen nephritis follow its administration. I do not hesitate to administer it in patients who have optic nerve involvement as a result of syphilis.

---

[2] Collins, Joseph, and Armour, Robert G.: The Treatment of Syphilitic Diseases of the Nervous System by Salvarsan.—THE JOURNAL A. M. A., June 22, 1912, p. 1919.

THE EFFECTS OF SALVARSAN ADMINISTRATION

The immediate effects, that is within the twenty-four hours, are variable. Their occurrence depends in a measure on the preparation of the patient and the correctness of the technic of administration. When every precaution is taken some patients nevertheless have a rigor, slight rise of temperature, up to 100, and usually diarrhea within five hours after the salvarsan has been given. In one instance only have I seen a patient have a sense of cardiac oppression after the injection and I have never seen pain, headache or backache which was not more properly attributable to lumbar puncture.

The remote after-effects, that is, after a few days, is almost invariably a feeling of buoyancy, increase of weight, and what is meant by improvement of the general health.

The contra-indications to the use of salvarsan are nephritis and advanced nephritis and advanced arteriosclerosis.

All things considered the intravenous method of administration is preferable. Neosalvarsan has advantages over salvarsan insomuch as it is more easily soluble; it does not need to be neutralized; it is probably less toxic and it is simplicity itself to prepare (namely, mix it with 150 c.c. of sterile freshly distilled water). Despite these advantages my belief is that it is an antisyphilitic agency quite inferior to salvarsan and that the results we have obtained from the administration of neosalvarsan are not so good as those from salvarsan.

What then, finally, is my message? It is that syphilis is still a scourge to our people, hidden in the folds of the cloak of shame. Its occurrence must be checked by enlightening the people, men, women and youth. Its activity must be curtailed by prompt, vigorous and appropriate treatment. Its manifestations, it matters not in what tissues or organs they appear, constitute syphilis and it is this and not the disease of the organ or tissue that must be treated.

37 West Fifty-Fourth Street.

THE DEMONSTRATION OF THE SPIROCHAETA PALLIDA IN THE BRAIN SUBSTANCE OF LIVING PARETICS (FORSTER AND TOMASCZEWSKI)

UDO J. WILE, A.B., M.D.
Professor of Dermatology and Syphilology, University of Michigan, Department of Medicine and Surgery
ANN ARBOR, MICH.

Following the demonstration by Noguchi of the *Spirochaeta pallida* in the stained specimens of the brain in general paralysis, Marie, Levaditi and Bauchowski[1] were able to demonstrate the organism from the fresh brain at necropsy by the dark field illumination. During the past month a cooperative finding of no less importance has been reported by E. Forster, assisted by E. Tomasczewski.[2] Employing the method of brain puncture, these authors have been able to demonstrate living spirochetes in the aspirated cortical substance. Their first report included six cases examined with positive findings in two. Twenty cases have been examined to July 28, and the organisms have been found in eight.

Through the kindness of Professor Forster I have been permitted to assist in two of these operations, to substantiate the microscopic findings, and to report herein the method of procedure.

The method of puncture is as follows: The patient's head is first shaved and the anterior portion of the skull thoroughly painted with tincture of iodin. The point of operation selected is over the frontal convolution from about ½ to 1 inch from the midline and well forward of the middle meningeal artery. The region is frozen with ethyl chlorid and a revolving dental drill is thrust quickly through the skin and deeper tissues. A few rapid revolutions of the drill in the hands of an assistant suffice to pierce the skull. The borer, or drill, is then removed and a long, thin trocar needle is inserted in the hole through the skin and bone; this is pushed firmly and deeply into the cortex. The wire obturator of the trocar is withdrawn and a syringe barrel is attached to the end of the needle. By suction, a small cylinder of brain substance containing both gray and white matter is drawn into the syringe, together with more or less fluid from the ventricle. This material, transferred to a sterile Petri dish, is examined at once with a dark field illumination. Thus far the organisms have been found in the gray matter only.

The operation is extremely simple. One has only to avoid the cerebral and meningeal vessels, and over the upper frontal region, well away from the midline, such danger is not encountered, nor is any important center disturbed by the operation. In all cases thus far examined, practically no pain has been experienced.

The discovery of Noguchi has once and for all effectually disposed of parasyphilis or metasyphilis, at least so far as the central nervous system is concerned. General paralysis is true syphilis of the brain. The finding of the organism in the living brain by Forster, besides finally establishing the proof of Noguchi's work, may, it is hoped, lead to important changes in the therapy of the disease, particularly in early cases in which the damage to the cortex is slight. The opinion has been expressed that the organism is not present in all cases of paresis. Considering, however, the small number of cases examined, with the relatively high percentage of positive findings (40 per cent.), together with the fact that in the brain puncture but a very minute portion of the cortex is examined, it would appear more rational to believe that the organism is present in all cases. A negative finding is obviously no indication of its absence.

It is not too much to hope that the demonstration of the spirochete in cases in which the cortical centers are as yet not greatly involved, and in the possible absence of other positive findings, may be followed by an arrest of the course of the disease under appropriate treatment.

It has hitherto been assumed by syphilographers that paretics could not transmit syphilis. The discovery, however, of the organism in the living brain of such subjects casts more than a shadow of doubt on this theory.

Knee-Jerks in Hysteria.—It requires great boldness on the part of any individual to diagnose hysteria in a case in which the tendon-jerks are absent. The plantar reflexes may be absent in a case of functional disease, hysteria, but the knee-jerks are increased.—J. S. Risien Russell, in *Clin. Jour.*

THE ADMINISTRATION OF SALVARSAN AND NEOSALVARSAN BY ENTEROCLYSIS

REPORT OF THIRTY-SEVEN INJECTIONS *

LUDWIG OULMANN, M.D.
Chief and Attending Dermatologist, German Hospital Dispensary
AND
J. L. WOLLHEIM, M.D.
Attending Genito-Urinary Surgeon, Philanthropic Hospital; Attending Urologist, German Hospital Dispensary; Adjunct Visiting Physician, City Home, Work-House and Penitentiary Hospitals, New York
NEW YORK

The method which we are about to describe is apparently unique, for in only three instances[1] have we found references in the literature to similar procedure.

The method which we use is simple, and the apparatus is not at all complex. The evening before treatment the patient is given a dose of saline cathartic to empty the bowels completely. He is then directed to take a rectal douche of soap solution about one hour before coming for treatment. If he is to be treated in the afternoon, we allow him to have a light breakfast and to take his enema one hour before the appointed time for treatment. If he is to be treated in the forenoon, he has no breakfast. We insist on three points: that the patient be hungry, thirsty and empty. He is then placed on the table and given a dose of morphin hypodermically, the dose varying from one quarter grain down, according to size and age. Children are given a dose of paregoric by mouth. This is given to relieve the patient of any possible irritation of the rectal tube, and also to aid in constipating his bowels. He is then placed on his right side, in the semiprone position, with the head of the table tilted down. We then pass the rectal tube or catheter, about a No. 20 French for adults, for a distance of about 12 inches or as far as possible. If the catheter is passed correctly it should be in the sigmoid flexure, as the rectum is supposed to be about 8 inches long in the average person. After the injection the bowels are constipated for from twenty-four to forty-eight hours. It may be of interest to note in passing that Dr. Chapin of New York has recently proved by means of the Roentgen ray, that suspensions of barium salts flow through the entire large intestine of children, to the ileocecal valve, when the suspension is just allowed to flow into the rectum through a short rectal tip or douche nozzle.

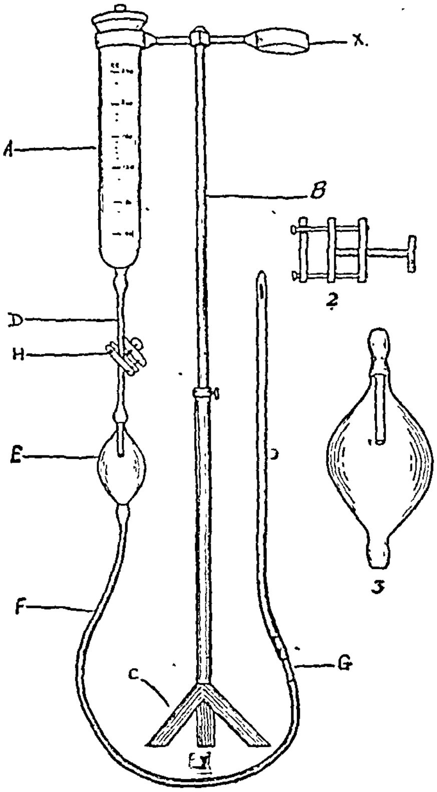
The solution is prepared exactly as in the intravenous method, except that we dilute to exactly 240 c.c. The reason for this will be stated further on. The solution is then poured into the apparatus.

APPARATUS

The apparatus is a cylindrical vessel (*A*) such as is found in the Boehm apparatus, graduated in 10 c.c., to 240 c.c., supported on an extension upright (*B*) and a solid base (*C*). Attached to this cylinder is a rubber tubing (*D*) about 6 inches long, at the other end of which is attached a special glass dropper-bulb (*E*), such as is used in the intravenous anesthesia apparatus, by means of which we can see the rate of flow. Attached to the distal end of the dropper-bulb is another piece of tubing (*F*) about 2 feet long to the distal end of which is attached a tapered glass connection (*G*). The rate of flow is easily regulated by a Hoffman cut-off (*H*), attached to the tubing (*D*), which allows a flow of any desired speed by the turning of a screw. This apparatus is so arranged that two patients can be treated at the same time, if a second cylinder, bulb, cut-off and tubing be attached to the apparatus at the ring (*X*). This improvised apparatus has given us complete satisfaction.

TECHNIC

The patient having been prepared as described is placed on the table and given his morphin or paregoric as the case may be. We then prepare the solution with warm water previously sterilized by boiling. The apparatus which was previously cleaned, either by allowing very hot sterile water to flow through it or by boiling, is filled with the solution. The rectal tube previously boiled is then inserted to about 12 inches, connected up to the tapered glass (*G*) of the apparatus, and the fluid allowed to drop. Now if the flow is regulated, so that it drops at the rate of 60 drops per minute, it will take just one hour for the 240 c.c. to pass into the patient. This is ample time for absorption and does not irritate the rectum, as we have proved a number of times. We have seen a very rapid injection retained and apparently absorbed with good effect, but we feel that we cannot recommend it. We also feel that the slow method which is practically a "Murphy drip" method is the better of the two.



Apparatus for the administration of salvarsan and neosalvarsan by enteroclysis.

We have given in this way thirty-seven injections to thirty patients. Of these injections five were with neosalvarsan and thirty-two were with salvarsan. We have seen no bad after-effects in general. One patient had a severe vomiting and weak spell, which necessitated a rest in the office for a few hours. This we believe was due to his having disobeyed our instructions, inasmuch as he had taken two glasses of beer and two hard-boiled eggs just before coming for treatment. Other than in this one case, we have seen no alarming ill effects. We have, however, seen a number of cases of moderate vomiting and urinary frequency following these injections. All of our patients were treated in our offices and returned home from there. The ages of our patients varied from 6 to 56 years. We have seen all the various manifestations of syphilis, such as chancres, genital and otherwise, rashes, condylomas, gummas and secondary and tertiary throat lesions, clear up with this method, and it is difficult to say whether or not the intravenous administration would have done so any more quickly.

---

* Read before the Yorkville (N. Y.) Medical Society, June 9, 1913.

[1] Weill, A. J.; Morel and Moriquand, G.: Administration of Salvarsan by the Rectum in Children, Bull. Soc. de pédiat. de Paris, xiv, No. 7; abstr., The Journal A. M. A., Dec. 14, 1912, p. 2190. Kolmer, J. A., and Schamberg, J. F.: Experimental Studies on Administration of Salvarsan by Mouth to Animals and Man, Jour. Exper. Med., May, 1912. Bagrow, S. L.: Salvarsan Administered by the Rectum, Berl. klin. Wchnschr., Jan. 15, 1912, xlix, No. 3.

Though technically this method may be attacked on the ground that we cannot demonstrate the exact amount of salvarsan absorbed, we feel that judging from our clinical work it is nearly all absorbed if given according to the directions previously laid down. Further, we believe that we are in a position to compare the results of this and other methods, and, judging from our work and the reports of those who tried our technic, that salvarsan and neosalvarsan by enteroclysis have a place in the therapy of syphilis and should be used whenever the intravenous method is refused or for any other reason cannot be given.

Theoretically one might object to the dropper bulb, because each drop falls through air. This objection may be valid for the first few drops, but as the air in the bulb is not renewed during the administration, there is little oxygen to attack the salvarsan and neosalvarsan. Again, as we have seen no toxic symptoms in this series, we believe that this objection is not practical and may be dismissed from consideration.

CONCLUSIONS

We believe from the literature and our studies that:

1. The administration of salvarsan and neosalvarsan by enteroclysis has a place in therapeutics.
2. In general it ought not to replace the intravenous method, because it is possible that, in passing through the intestinal mucous membrane or the liver after absorption, some of the salvarsan may be changed chemically, and in that way its therapeutic effect may be less per unit of dosage.
3. It should be used in children in preference to other methods.
4. It should be the method of choice when the intravenous method is not feasible.
5. The subject is worthy of further study to determine the exact place of this method in the administration of salvarsan and neosalvarsan.

REMOVAL OF A FOREIGN BODY INTRODUCED INTO THE UTERINE CERVICAL CANAL TO PREVENT CONCEPTION

Aimé Paul Heineck, M.D., Chicago

Foreign bodies are sometimes introduced into the uterine cavity for the purpose of terminating an undesired pregnancy. Most frequently, they are employed in the absence of any legitimate indication.

These foreign bodies are responsible for a certain number of punctured and perforating wounds of the body and of the cervix of the uterus, inflicted by way of the vaginal canal. Some foreign bodies also have been inserted into the cervical canal to be retained more or less permanently; some of these devices are introduced and retained in the uterine cervical cavity merely to prevent conception. That their value as such is debatable, is amply demonstrated by what follows:

I have lately removed from the uterine cavity of several patients referred to me by other physicians a device which had been introduced into the uterine cervical canal with the positive assurance that conception was impossible as long as the "Jentsch self-retaining uterine tube" remained in the womb. Much to their astonishment and chagrin, these patients became pregnant, and aborted at various periods of gestation. In each of these cases, the uterine hemorrhage attending the abortion was unusually profuse, and in each, I experienced some difficulty in removing the device. In all of the cases, the placental and other ovular débris had to be removed instrumentally.

Mrs. F., aged 25, came into my service at the Jefferson Park Hospital on account of profuse uterine hemorrhage of about three days' duration. Interrogation and examination of the patient established the diagnosis of incomplete abortion. The patient could not believe that she was pregnant as she had purchased the self-retaining uterine tube and had had it introduced into the cervical canal on the assurance that it afforded absolute protection against the occurrence of pregnancy. A careful vaginal examination failed to detect the instrument, and the patient was in doubt as to its expulsion.

Expectant measures brought no relief, and the hemorrhage continuing, the patient was surgically prepared, anesthetized, and the cervical canal dilated. The so-called "protecting device" had escaped into the uterine cavity, and I could not have removed it without lacerating the uterine tissues, if I had not, to facilitate its extraction, made a complete unilateral division of the entire vaginal portion of the cervix. The self-retaining uterine tube was then removed, the uterine cavity emptied of the débris of a four months' ovum and the divided cervix sutured. Recovery was uneventful.

From my experience in the removal of these tubes, I would make the following statements:

1. Once inserted, they are difficult to remove; in two of my patients, a unilateral division of the vaginal portion of the cervix was required to effect the extraction of the instrument.
2. They do not prevent conception.
3. They not uncommonly induce abortion or miscarriage.
4. They may cause infectious phenomena productive of invalidism.

1809 South Trumbull Avenue.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

ELECTR-HG.—Electromercurol.—Electr-Hg is a colloidal suspension of mercury equivalent to 0.1 per cent. metallic mercury (Hg) and containing a small percentage of sodium arabate.

Electr-Hg is prepared by passing an electric current in the form of an arc between two mercury electrodes in distilled water. It is made stable by the addition of sodium arabate, which is prepared by acting on acacia (gum arabic) with hydrochloric acid precipitating the resulting arabic acid with alcohol and neutralizing the arabic acid with sodium carbonate.

Electr-Hg is an odorless, tasteless liquid appearing transparent and brown in color by transmitted light and opaque and gray by reflected light. The addition of potassium cyanide solution or of strong nitric acid yields clear, colorless solutions. The nitric acid solution responds to tests for mercury.

Actions and Uses.—Electr-Hg is claimed to have an action similar to that of the soluble salts of mercury. Locally it is said to produce no pain when given by intramuscular injection, and to leave no induration.

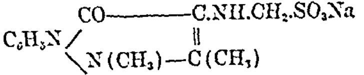
Dosage.—It is injected intramuscularly and intravenously in doses of 5 c.c. per day. For the intraspinal injection the dose is from 1 to 2 c.c., injected once a month or less frequently according to the effects it produces.

Electr-Hg is marketed in ampules only, in a non-isotonized condition. The package contains a physiologic salt solution with directions for the extemporaneous isotonization of the preparation before the injection.

Manufactured by Comar and Cie., Paris, France. No U. S. patent or trademark.

Ampoules Electr-Hg, 5 Cc.—Each ampule contains electr-Hg 5 Cc. (75 minims).

MELUBRIN.—Melubrin is sodium 1-phenyl-2,3-dimethyl-5-pyrazolon-4-amido-methan-sulphonate,



$$\begin{array}{l} \qquad\qquad \mathrm{CO}\text{————}\mathrm{C.NH.CH_2.SO_3Na} \\ \mathrm{C_6H_5N}\diagup \qquad\qquad\qquad \| \\ \qquad\qquad \diagdown\mathrm{N(CH_3)—C(CH_3)} \end{array}$$

the sodium salt of 1-phenyl-2,3-dimethyl-5-pyrazolon-4-amido-methan-sulphonic acid, differing from antipyrine, $C_{11}H_{12}N_2O$, in that a sodium-amido-methan-sulphonate group, $.NH.CH_2.SO_3Na$, has replaced a hydrogen atom of the pyrazolon group.

Melubrin is prepared by allowing a solution of formaldehyd bisulphite to act on 1-phenyl-2, 3-dimethyl-4-amido-pyrazolon, and purifying the resulting product by recrystallization.

It is a white, odorless, almost tasteless crystalline powder, readily soluble in water, but slightly soluble in alcohol. The aqueous solution is neutral in reaction but unstable.

If about 0.2 Gm. of melubrin dissolved in 5 Cc. of water be boiled with 3 Cc. of diluted hydrochloric acid, sulphur dioxid and formaldehyd will be liberated.

If ½ of the solution thus formed be treated with 3 drops of sodium nitrite solution and 5 Cc. of an alkaline solution of beta-naphthol, a red precipitate will be produced.

If the remainder of the above solution be treated with 1 Gm. of sodium acetate and 15 Cc of a saturated aqueous benzaldehyd solution, a yellowish white, flocculent precipitate will be formed which, when washed and dried, will melt at 173 degrees.

If a small quantity of melubrin be moistened with hydrochloric acid, it will respond to the flame test for sodium.

If a 10 per cent. aqueous solution of melubrin be made alkaline with ammonia, saturation with hydrogen sulphide should produce no change.

If 0.5 Gm. of melubrin be thoroughly mixed with 4 Gm. of sodium nitrate and gradually heated, 4 Cc. of concentrated sulphuric acid added to the resulting mass, and the mixture heated till no further white fumes are produced, the resulting substance powdered and mixed with 10 Cc. of saturated stannous chlorid solution, no darkening should occur within 1 hour.

If 0.4 to 0.5 Gm. of melubrin be weighed to a platinum dish, treated with dilute sulphuric acid, and heated to constant weight, the sodium sulphate thus formed should weigh 0.2160 to 0.2250 Gm. for each Gm. of material used, representing a sodium content of 6.99 to 7.28 per cent.

Actions and Uses.—It is claimed that melubrin in ordinary or even large doses is not toxic. In moderate doses it is said to have almost no effect on the circulation or respiration. It acts as a powerful antipyretic in fever and is analgesic.

Melubrin is said to be useful in painful affections, such as sciatica and other neuralgias, and as an antipyretic in various febrile affections. It is said to have effects similar to salicylates in acute rheumatism.

Dosage.—1 to 2 Gm. (15 to 30 grains). The larger doses are recommended for the treatment of rheumatism. It is claimed that as much as 10 Gm. (150 grains) may be given daily.

Manufactured by Farbwerke vorm. Meister Lucius and Bruening, Hoechst, a.M., Germany (Farbwerke-Hoechst Co., New York). U. S. Patent No. 1,056,881. (March 5, 1913; expires 1930). U. S. trademark applied for.

ACNE VACCINE.

Cutter Laboratory, Berkeley, Cal.

Acne Bacillus Vaccine.—Acne Bacillus Bacterin.—Each Cc. contains 50 million killed acne bacilli suspended in physiologic salt solution with 4/10 per cent. trikresol. Dose, from 5 to 50 million killed bacteria.

BACILLUS COLI VACCINE.

Cutter Laboratory, Berkeley, Cal.

Coli Vaccine.—A suspension of the Bacillus coli communis in physiologic salt solution with 4/10 per cent. trikresol. Containing 50 million killed Bacilli coli per Cc. Dosage from 10 to 100 million.

PNEUMOCOCCUS VACCINE.

Cutter Laboratory, Berkeley, Cal.

Pneumococcic Vaccine.—Pneumococcic Bacterin.—A suspension of mixed strains of the Diplococcus pneumoniae in physiologic salt solution with 4/10 per cent. trikresol. Containing 50 million killed pneumococci in each Cc. Dosage, from 10 to 100 million.

STAPHYLOCOCCUS VACCINE.

Cutter Laboratory, Berkeley, Cal.

Staph-Acne Vaccine.—Staph-Acne Bacterin.—A mixture of killed staphylococci and of killed acne bacilli in physiologic salt solution with 4/10 per cent. trikresol; each Cc. containing 500 million staphylococci and 50 million acne bacilli or in like proportions in greater or lesser counts. Dosage from 100 million to 2 billion.

Staphylococcic Vaccine.—A suspension of the Staphylococcus aureus, albus and citreus in physiologic salt solution with 4/10 per cent. trikresol. A suspension of various strains of staphylococci containing about 500 million to each Cc. Dose, from 100 million to 1 billion killed bacteria.

BACILLUS PYOCYANEUS VACCINE.

Cutter Laboratory, Berkeley, Cal.

Pyocyaneus Vaccine.—A suspension of mixed strains of killed bacillus pyocyaneus, in physiologic salt solution with 0.4 per cent. trikresol, 1 Cc. containing about 50 million killed bacilli.

ANTIGONOCOCCUS SERUM.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Co., New York.)

Antigonococcus Serum.—Marketed in a special syringe containing 10 Cc., with sterile needle.

ANTIMENINGOCOCCUS SERUM.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Co., New York.)

Antimeningococcus Serum (Antimeningitis Serum).—Marketed in an aseptic glass cylinder containing 15 Cc. with special sterile needle and stylet.

ANTISTREPTOCOCCUS SERUM.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Company, New York.)

Antistreptococcus Serum.—Marketed in an aseptic glass cylinder with sterile needle and rubber bulb connection; the cylinder contains 50 Cc.

Antistreptococcus Serum, Polyvalent.—Marketed in a special syringe containing 10 Cc.

ANTIPNEUMOCOCCUS SERUM.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Co., New York.)

Antipneumococcus Serum.—Marketed in an aseptic glass cylinder with sterile needle and rubber bulb connections; the cylinder contains 50 Cc. Also in a special syringe containing 10 Cc., with sterile needle.

NORMAL HORSE SERUM.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Co., New York.)

Normal Horse Serum.—Marketed in a special syringe containing 10 Cc., with sterile needle. Also in an aseptic glass vial, containing 100 Cc.

STREPTOCOCCUS VACCINE.

Cutter Laboratory, Berkeley, Cal.

Streptococcic Vaccine.—Streptococcic Bacterin.—A suspension containing in each Cc. 50 million of killed streptococci in physiologic salt solution with 4/10 per cent. trikresol. Dose, from 5 to 50 million.

Lederle Antitoxin Laboratories, New York City. (Schieffelin and Co., New York.)

Scarlet Fever Treatment.—This product is marketed in four syringes containing respectively, 50 million, 100 million, 200 million and 400 million killed bacteria. Also marketed in four packages of two vials, each containing 50 million, 100 million, 200 million and 400 million killed bacteria. Also marketed in 20 Cc. vials in four strengths, 1 Cc. containing respectively, 50 million, 100 million, 200 million and 400 million killed streptococci.

Scarlet Fever Prophylactic.—This product is marketed in a package of three syringes containing, respectively, 250 million, 500 million, and 1 billion killed streptococci from scarlet fever cases. The content of these syringes should be injected subcutaneously at intervals of seven days. Also marketed in a package of three vials, each containing respectively, 250 million, 500 million and 1 billion killed bacteria.

TYPHOID VACCINE.

Cutter Laboratory, Berkeley, Cal.

Typhoid Vaccine.—A suspension of killed bacilli in physiologic salt solution with 4/10 per cent. trikresol, containing 50 million killed typhoid bacilli of various strains in each Cc. Dosage from 5 to 50 million every 3 to 5 days.

Typhoid Prophylactic.—A suspension made from a single strain, viz., that employed by the United States Army. Each Cc. contains 1 billion killed typhoid bacilli. Put up in packages containing 3 bottles. Bottle No. 1 contains 500 million; bottle No. 2, 1 billion; bottle No. 3, 1 billion killed typhoid bacilli.

National Vaccine and Antitoxin Institute, Washington, D. C.

Anti-Typhoid Vaccine (Immunizing).—This vaccine is prepared according to the technic of Russel from the strain used in the U. S. Army. It is marketed in three syringes containing respectively 500, 1,000, and 1 billion killed typhoid bacilli; also in ampouls containing the same doses.

DIFFERENTIAL IMPORTANCE OF THE ALCOHOL CONTENT OF THE BLOOD

We have not increased our information concerning the mechanism by which the body defends itself and decreases its susceptibility to simple chemical poisons to anything like the extent to which we have advanced our knowledge about immunity to bacteria and to foreign proteins. That the processes involved in acquiring resistance to the two classes of poisons are quite different seems to be established, and for the most part the simple poisons seem to be attacked by simple chemical processes, such as oxidation, precipitation or union with simple chemical radicals. There is no more marked illustration of acquired tolerance to a chemical poison than that furnished by alcohol, and in view of its significance for the general problems of immunity or adaptation, a recent study of the alcohol content of the blood during different conditions is of considerable importance.[1]

The author of this article, Schweisheimer, first took up the old problem of the normal occurrence of alcohol in the blood and tissues, concerning which there is disagreement. He found that human blood from subjects who have not had any alcohol does contain minute quantities of volatile, oxidizable substance, corresponding to about 0.003 per cent., a finding supporting results previously obtained with animal blood and tissues. Unfortunately, there seems to be no available method which will determine positively whether these minute quantities of volatile material really are alcohol or not, for there are other organic substances which might be present and, in the quantities in which they exist, indistinguishable. Schweisheimer believes that the material in question is, at least in large part, alcohol.

The alcohol content of the blood of persons in various stages of intoxication, on the other hand, is quite considerable, and in a general way corresponds to the degree of intoxication; but there is a striking difference in the curve of the alcohol content in the blood of habitual drunkards and of abstainers. In persons unaccustomed to alcohol the maximum proportion of alcohol in the blood is reached in from about one and one-half to two hours after drinking a considerable quantity of wine (about 1 liter of a wine containing 10.35 per cent. of alcohol), and remains at nearly the same concentration for about five or six hours, then gradually falls, and by the twelfth hour is nearly all gone. The habitual drunkard, however, shows a quicker rise in the alcohol content of the blood to a maximum, which is maintained for but a comparatively short time, about two hours, and then the curve rapidly falls to near zero. Furthermore, in the alcoholic subject the maximum content is much lower than with the abstainer given the same amount of alcohol. When the blood contains over 0.02 per cent. alcohol the subject may show symptoms of intoxication, and usually does when it reaches 0.05 per cent. With the dosage mentioned, the content of alcohol in the blood reached from 0.1 to 0.15 per cent. in some cases, while in drunken men brought into the hospital amounts from 0.12 to 0.23 per cent.[2] were found.

The analytic results agree well with the recognized features of the influence of alcohol on the accustomed and the unaccustomed, and indicate that the former in some way get rid of their alcohol more rapidly than abstainers. Presumably this is by a more active oxidation, but in what tissue or through what agency is as yet undetermined. The results obtained with nondrinkers, moderate drinkers and confirmed drunkards show a progressive ability to keep down the quantity and persistence of alcohol in the blood, indicating that this faculty is of gradual acquirement. As with equal concentrations of alcohol in the blood of drunkards and non-drinkers, however, the latter show much greater evidence of intoxication, it would seem that there are other factors to be considered. Probably the grave danger of acute alcoholism in the unaccustomed drinker lies especially in the long period during which the maximum alcohol content persists in the blood.

It would seem that the accurate determination of the alcohol content of the blood is not difficult or time-consuming when once the apparatus is set up and the necessary experience gained. This being so, there is a diagnostic measure offered which should be of much value in those puzzling cases of coma in which alcoholism is suspected. In every large city mistakes are repeatedly being made in these cases, often with serious results when a diagnosis of alcoholism and a jail floor are provided for a man who has a skull fracture, uremic coma or some other dangerous and perhaps curable condition. If a routine analysis of the blood for alcohol content were made before a diagnosis of alcoholic coma would be accepted, such mistakes could be largely eliminated. A single drink will give grounds for a diagnosis of alcoholism if the diagnostician relies on his olfactory sense alone, but it will not so raise the alcohol content of the blood as to warrant such a diagnosis.

[2] In our abstract of this article through an error the figures were given ten times too high. The proportion should have been given "per thousand," instead of "per cent."

DIABETIC CONDITIONS DUE TO STARVATION

It has been known for some time that during a period of inanition the tolerance of animals for carbohydrate may be greatly diminished. Whether this is likewise true in the case of man cannot be stated with certainty so far as chronic starvation is concerned, for the observations on record are insufficient to permit of any convincing conclusion in the matter. When these phenomena of "starvation diabetes" were first noted it was suggested that the explanation lay in an inability of the organism to utilize sugar as efficiently during a period of inanition as during ordinary conditions of well-being. Obviously such a statement is at best hypothesis of the vaguest sort and fails to afford any concrete idea of the nature of the deficiency involved.

Not long ago, under the heading of "Acid Diabetes,"[1] we discussed the alleged influence of acids on the metabolism of carbohydrates. We spoke of the suggestion from von Noorden's clinic that even comparatively small quantities of acid introduced into the organism can "mobilize" glycogen in the body, giving rise in this way to hyperglycemia and a consequent glycosuria. The experimenters further believed that this sequence of events is quite independent of the adrenals, which have of late been called on to explain the genesis of diverse conditions leading up to elimination of sugar by the kidneys. In the case under discussion the liver was designated as the presumable point of the sugar-liberating attack by the acids.

From such an experimental starting point it was a logical sequence to inquire whether various pathologic conditions attended with a development of acid in the disturbed metabolic processes themselves, rather than the contribution of acid from outside the body, might not sometimes be responsible for glycosuric or diabetic phenomena like those described. We use the term "diabetic" here in the sense of lowered tolerance for, or utilization of, carbohydrates. And since in starvation such conditions may arise, it has been asked whether a pathologic development of acid might not be responsible. In the first medical university clinic in Vienna, Elias and Kolb,[2] following the lines of their earlier studies on acid and diabetes, have demonstrated that, in dogs at least, the "starvation diabetes" is actually accompanied by a greater acidity of the blood and by an unmistakable hyperglycemia, independent of adrenal perturbations. These consequences are apparently not attributable to defects of absorption or unusual permeability of the kidneys. They involve some process of intermediary metabolism and can be more or less effectively repressed by administration of alkali, the natural antagonist of acids.

A few years ago it would have seemed far-fetched to look upon starvation as anything fundamentally pathologic. The consequence of lack of food was assumed to be a purely negative one, in which certain physiologic processes ceased or slowed down. To-day, prolonged inanition, whether voluntarily induced or the enforced result of disease, is no longer to be regarded as a purely indifferent situation. Metabolism in starvation is admittedly abnormal.

ERADICATING ROCKY MOUNTAIN SPOTTED FEVER

The work of clearing the mountains and valleys of the spotted fever district in Montana, inaugurated some years ago, is still being carried on vigorously. Since the death of Dr. McClintic, who contracted the fever while working in Montana, Dr. L. D. Fricks of the United States Public Health Service has carried on the work in the Bitter Root Valley. In a recent report in which he discusses the method heretofore employed in destroying the ticks, such as cleaning and cultivating the land, burning over foot-hills and slashes, killing small wild mammals, dipping domestic animals in solutions of arsenic, and removing ticks by hand from domestic animals, all of which are cumbersome and expensive to apply and only in a measure effective, Fricks[1] gives the results of some experiments with sheep as a means of eradicating the tick. The methods previously employed have been used for three years without greatly diminishing the number of ticks or the number of deaths from spotted fever.

The infection in its most virulent form exists in certain districts on the west side of the Bitter Root River, a region still in the primitive state. On the east side of the river, where the territory has been cultivated and where most of the efforts to eradicate the tick have been employed, there are comparatively no ticks; but in small portions of the territory on the west side the ticks exist literally in millions and their eradication by the methods named seems almost hopeless. It is found, however, that the ticks do not flourish for any considerable length of time in the region pastured by sheep. Experiments by Fricks and his assistants during the present year show some rather interesting results. As summarized in the report, 87 per cent. of 295 ticks placed in the wool of unshorn sheep were found dead. The majority of the ticks recovered from sheep grazing naturally over the tick-infested territory were dead. It is known that the fertilization of the female ticks takes place while on the larger domestic animals. Sheep seem to be particularly unsuitable for tick propagation and many of the females recovered from the sheep appeared not to have been fertilized. Comparatively few ticks, either dead or alive, were found on the sheep after they had been shorn. In this investigation only sixty-one sheep were employed. Fricks proposes to test the method still further in the coming season by placing a flock of two thousand sheep on some tick-infested range on the west side of the Bitter Root River organs functioning in the production of energizing internal secretions. Over these organs—the thyroid, the adrenals, the hypophysis—the "contact ceptors" have no control, if we may trust laboratory evidence. Apparently no amount of physical trauma inflicted on animals will cause hyperthyroidism or increased epinephrin in the blood, while fear and rage are said to occasion them. As Crile says, this is a statement of far-reaching importance and is the key to an explanation of many chronic diseases such as are associated with the intense stimulation of the special senses in human relations. We are reminded that chronic emotional stimulation may fatigue or exhaust the brain, and may cause cardiovascular disease, indigestion, hyperthyroidism, diabetes and insanity even.

These purely mechanistic conceptions of some of the phenomena of the nervous system frequently run counter to the inherited traditions regarding the make-up and behavior of the human organism; but they are here to be dealt with and, what is more important, they are fruitful in practical suggestions derived therefrom.

Current Comment

THE "FRIEDMANN INSTITUTES"

Once more it should be stated that the so-called Friedmann cure for tuberculosis is utterly discredited. All reliable reports regarding the treatment of patients by Friedmann's method seem to show either that it is actually injurious or else that it is less efficient than other well-known and less dangerous means of treatment. While attention has already been called to the facts, it is worth while again to remind our readers that: 1. Dr. Mannheimer reported on the results of eighteen cases in New York in which the Friedmann "treatment" was used, and stated that in not a single one of the eighteen cases was there definite improvement to date that could be attributed to the "treatment." 2. A committee of some of the foremost physicians of Canada was appointed to watch the patients inoculated by Dr. Friedmann in the Canadian hospitals. These physicians made a similarly unfavorable report. 3. Dr. Anderson, acting under the authority of the United States government, watched the progress of the patients treated by Dr. Friedmann in this country. He also gave an unfavorable opinion as to the effect of the treatment. 4. The Friedmann "treatment" has been condemned by German physicians generally. 5. A report from the Rhode Island State Sanatorium on the results in 120 patients treated by the Friedmann method states that the patients "have shown none of the immediate and wonderful results reported by Friedmann," but that, "on the contrary, about 17 per cent. of the cases" are worse than they might have been expected to be under ordinary sanatorium treatment. This, and more is true, and yet the company which is exploiting this so-called cure is, apparently, able to find physicians who are willing to aid in this inhuman business. After all, this might be expected; it has always been possible to find men willing to do disreputable work, if sufficient financial inducements are offered. While we believe that the medical profession harbors but a small proportion of men of this type, it has some within its ranks who are willing to sell their birthright of professional decency for a mess of pottage. As has been previously said, the scheme of floating Friedmann institutes in different states successfully evades any reprisal on the part of the federal government. It therefore devolves on the various states to take such action as is necessary to prevent the heartless exploitation of the unfortunate consumptives within their borders.

THE CIRCULATION AND MUSCULAR EFFICIENCY

It is a familiar observation that the circulation is affected by muscular effort. One of the features commonly observed during muscular exercise is an augmented blood-pressure. No one seems to have paid any attention to the reverse situation, namely, the possible influence of altered circulatory conditions such as changes in arterial pressure on the efficiency of the muscular apparatus. Dr. Gruber[1] of the Harvard Medical School has investigated this aspect of the relation of the circulation to muscular ability, and particularly what effect changes of arterial pressure, either increase or decrease, may exert on neuromuscular fatigue. He has found that there are unmistakable evidences of alterations in muscular vigor demonstrable in an experimental way. When the circulation is improved by increasing the arterial blood-pressure the intensity of the contractions of skeletal muscles may be decidedly increased. This is true, however, only when the pressure is comparatively low to begin with, that is, below from 90 to 100 mm. of mercury. When the initial pressure is above this level little improvement ensues from a further enforced rise. Correspondingly, as the blood-pressure or the circulation is decreased, the vigor of the muscular contractions is lowered—here again this deterioration takes place only when the arterial pressure falls below the limits quoted before. Evidently there is a critical region of arterial pressure which conditions the most satisfactory working power. This is easily understood when we remember that fatigue products accumulate in a muscle when it is doing work. As the pressure rises, thus bettering the blood-flow through the active muscle, these products are carried away more rapidly, and more oxygen is brought to places where it is most needed.

THE PASSING OF THE BASEMENT HOME

This month the basement as a living-room will, officially, pass out of existence in Missouri. The movement is significant as the beginning of a realization by the legislative bodies of the country that the conservation of public health is the most important factor in political economy. The basement living-room, coupled with the daily toil of children in factories and sweatshops, has enormously increased the death-rate among the children of the lowly. Particularly related to a dark, damp basement home is a lowered condition of vitality, which predisposes to infection by tuberculosis and aids the vicious spreading of all the acute exanthems. If, in Missouri, where conditions of population are at most not crowded, such a step has seemed necessary, how much more must such a law be needed in the densely packed tenements of New York, Chicago and other metropolitan cities? Missouri, in the past, has insisted that she must "be shown"; here, indeed, she has pointed the way for her sister states.

---

THE HETEROGENEOUS LIPOIDS

The term "lipoids" is used as a generic name for those constituents of living cells which can be extracted by ether or similar solvents. It is a biologic rather than a chemical term, and includes substances of quite different chemical composition such as cholesterol, which is an alcohol, and lecithin, which is a complex fat. The impropriety of putting these two substances in the same class biologically is shown by recent research which demonstrates that they possess physiologic actions which are diametrically opposed to each other. The companionship of lecithin and cholesterol in the so-called lipoids of animal cells and tissues is appreciated by biologic chemists; but the differentiation of the respective rôles of these compounds in physiologic phenomena is still largely a task of the future. Observations derived from the field of the study of immunity reactions have furnished instances which lead one to believe that in many cases these two classes of compounds, so unlike in chemical structure despite their superficial resemblances in point of solubility and physical behavior, are antagonistic in biologic deportment. Thus in the phenomena of hemolysis, cholesterol and lecithins (phosphatids) undoubtedly manifest quite unlike reactions in relation to the red blood-corpuscles. A comparable illustration of similar differences has been furnished by a recent study of phagocytosis.[1] Cholesterol, even in small proportions, vigorously inhibits the phagocytic response of healthy leukocytes; but the inhibition can be completely overcome by means of lecithin. This furnishes only an added instance that warns us against drawing any sweeping conclusions as to the functions of heterogeneous mixtures of ether-soluble tissue components—responses that are referred to as "lipoid reactions" or "lipoid phenomena." Biochemical research has at length reached a point at which it becomes necessary to distinguish, as clearly as our present information will permit, between the physiologic behavior of the individual representatives of an interesting and potent group of tissue components.

THE BEHAVIOR OF DIFFERENT FATS IN THE STOMACH

The fact that ingested fats distinctly retard both the secretory functions and the motility of the stomach is applied in a practical way in clinical medicine, particularly in gastric hyperacidity and hypersecretion. This raises the question as to whether or not there are any differences in the physiologic behavior of fats in the stomach depending on the quality, physical properties and texture of the material fed. The edible fats of commerce vary widely in these respects, ranging from the liquid olive-oil, on the one hand, to the more consistent mutton fat, on the other. A recent study of the subject[1] has made it clear that they are discharged from the stomach into the intestine at varying rates depending on their melting-points—an index of texture—and their viscosity. It matters little whether the fats are emulsified or not; they leave the stomach relatively more slowly if their melting-point is higher and their viscosity greater. Among familiar examples, therefore, olive-oil, beef fat and mutton fat are transported out of the stomach at a speed in the order mentioned, the harder mutton tallow being delayed longest under comparable circumstances of feeding. Fats administered in the form of emulsions along with other food are discharged from the stomach more promptly than emulsified fats administered in a comparable way. The delay in the release of fat is, in general, greater in the absence of other foods than when there is some dietary admixture. From the experiments which have been made it appears that fats are promptly released from any intimate mixture with other nutrients in the company of which they may have been fed; so that they tend to enter the intestine by themselves. The degree of inhibition which they exert on the progress of their companion food materials through the pylorus depends in turn on their physical properties: the more viscid fats retard the discharge of other (non-fat) foods less than the more liquid types. It follows, therefore, that the dietotherapeutist cannot only employ fats to suit his needs in relation to the performances of the stomach, but by exercising discrimination in respect to texture and state of emulsification he can also further modify or regulate the results which he is aiming to accomplish.

THE CEREBROSPINAL FLUID IN CHEMICAL DIAGNOSIS

A chemical diagnosis of nervous and mental diseases can scarcely be said to exist at present. Doubtless there are changes in the composition and metabolism of the nervous tissues, particularly the brain, which attend marked pathologic alterations in the structures. But inasmuch as the entire nervous system comprises only about 2 per cent. of the total body in point of bulk, one can well understand why even very considerable contributions from an organ like the brain should make only an insignificant distinctive impression on the composition of the blood or urine or feces that represents the sum total of the physiologic transformations of all the other organs and tissues as well. The most promising outlook for the discovery of chemical diagnostic signs of alterations in nervous tissues lies in the direction of the cerebrospinal fluid which, bathing the tissues, is, as it were, the immediate representative of the waste and wear of the cells and ought to contain the products of their metabolism in most concentrated and least altered form. We need scarcely add that from the point of view of bacteriologic diagnosis the clinical examination of the cerebrospinal fluid has already proved to be of great assistance in practice. Chemical studies of the cerebrospinal fluid have not been wanting in the past, and some of the alleged clinical tests that are in use are in reality chemical reactions. Broadly speaking, little progress has yet been made in this field, probably because the investigations have never been conducted on a sufficiently comprehensive scale to bring out characteristic alterations unquestionably attributable to definite diseased states. Dr. R. V. Stanford,[1] research chemist of the Cardiff City Mental Hospital in Great Britain, has reported a series of determinations of the specific gravity of the cerebrospinal liquor which suggests the existence of detectable differences associated with degenerative changes in the central nervous system. The probability that, in contrast with purely functional psychoses, progressive paralysis and severe dementia are accompanied by a loss of tissue substance is attested by the anatomic findings and also made likely by Stanford's observations. Thus he has noted the specific gravity of the cerebrospinal fluid to be greater in progressive paralysis (from 1.0045 to 1.0047) than in other nervous diseases (from 1.0043 to 1.0045), with the exception of epilepsy. The concentration in progressive paralysis appears to increase with the progress of the disease, as one might expect on the hypothesis of progressive disintegration. Lower figures were obtained only in cases of remission.

Medical News

ARKANSAS

Fire Destroys Sanatorium.—The fire which swept Hot Springs, September 5, causing a destruction of more than $3,000,000 worth of property, burned the Ozark Sanatorium with a loss of $45,000, partially covered by insurance.

New Officers of State Board.—At the annual meeting of the State Medical Board of the Arkansas Medical Society, held in Little Rock, August 13, Dr. J. C. Wallis, Arkadelphia, was elected president; Dr. W. S. Stewart, Pine Bluff, secretary, and Dr. M. Fink, Helena, treasurer.

Plans Bureau of Vital Statistics.—The State Board of Health is planning to establish a Bureau of Vital Statistics as provided for by an act of the legislature. The Federal Government has detailed F. L. Watkins, special agent of the Census Bureau, to have charge of the work and to assist the state board.

Free Anti-Rabic Treatment.—The Arkansas State Board of Health announces that it is prepared to give free anti-rabic treatment to all persons bitten by dogs or other animals suspected of being rabid. To secure this treatment, it is necessary for the applicant to obtain an order on the board from the county judge for the treatment.

Personal.—Dr. E. F. Winegar, Hot Springs, accused of dividing fees for medical services, was acquitted by the jury, August 22. Dr. Winegar has reopened his sanatorium which was burned March 7.——Dr. J. E. Phillips, local surgeon for the Iron Mountain System at Fort Smith, who was operated on recently in St. Louis, has returned home, convalescent.

State Health Car for Arkansas.—At a recent meeting of the Arkansas County Medical Society, held at Stuttgart, Dr. T. B. Bradford, Cotton Plant, announced that he was working on a proposition to provide a health car to travel around the state, disseminating information regarding the prevention of disease, distributing literature and carrying with it a corps of lecturers for the education of the people.

CALIFORNIA

Seeks Site for Hospital.—Dr. John A. Reily of the State Hospital, Patton, is searching for a site for another hospital for Southern California. The institution is to cost about $90,000 and will occupy a site of about three hundred acres.

Hospital Notes.—The Universal City Hospital was formally dedicated August 8. Dr. Rollin French is in charge of the institution.——The City Council of Los Angeles has approved the plan of Drs. J. A. Jackson and F. L. Hough to establish a branch of the Emergency Hospital in Hollywood.——The Haben Hospital, Monrovia, recently erected by the Misses Haben, at a cost of $15,000, was opened August 8. The building is 50x90 feet and of bungalow design.——The new Pomona Valley Hospital, erected at a cost of $60,000, at Pomona, was formally opened the last week in August. The building is of concrete construction and practically fireproof and can accommodate twenty-five private patients.

COLORADO

Baby Clinic Abandoned.—Lack of patronage has caused Deputy Health Commissioner Hays and Dr. W. H. Sharpley, superintendent of the County Hospital, Denver, to abandon the plan to establish a baby clinic at that institution.

Personal.—Dr. Walter Morritt, superintendent of the Minnequa Hospital and head of the sociologic department of the Colorado Fuel and Iron Company, has resigned to accept the position as superintendent of the Beth-El Hospital, Colorado Springs.

FLORIDA

State Board Will Control Hydrophobia.—The State Board of Health of Florida has made arrangements to furnish the Pasteur treatment free to physicians of the state and also to make examinations of animals suspected of rabies.

Hospital Notes.—A site has been purchased in Pensacola on which it is understood that the Roman Catholics will erect a large hospital building.——The new St. Luke's Hospital, Jacksonville, is almost ready to receive patients and expects to open formally October 1.

Personal.—Dr. Hiram Byrd, Jacksonville, announces that he has severed his connection with the State Board of Health to be associated with the Grand View Sanatorium for Tuberculosis, Port Orange, Fla.——Dr. George W. Holmes, Sharpes, has returned after a trip to the Canal Zone and West Indies.

GEORGIA

New Officers.—Eighth District Medical Association at Elberton, August 20: president, Dr. W. J. Mathews, Elberton; secretary, Dr. Edward M. Coleman, Athens (reelected).

New Hospital.—The new hospital which the ladies of the Americus Hospital Association are to erect in that city, is to be located on the South Side of the city, and will be constructed of brick with granite trimmings, will contain thirty rooms, and will, it is expected, be ready to open before the end of the year.

ILLINOIS

Personal.—Drs. George N. Kreider and L. C. Taylor, Springfield, have returned from Europe.——Dr. and Mrs. W. Grant Hatch, Rockford, left for Europe, September 3.——Dr. J. Leslie, Elwin, celebrated his seventy-fifth birthday anniversary September 1.

Hospital for Fraternal Order.—The following staff of physicians has been appointed for Mooseheart, the industrial home of the Loyal Order of Moose: Drs. H. A. Brenneke and George A. Darmer. A building for the hospital is now under construction and work on the permanent building will be started this fall.

More State Hospitals Needed.—The State Charities Commission, in its annual report, urges the establishment in large centers of population of psychopathic hospitals for the care and treatment of the acute varieties of insanity, at which the commitment will be purely voluntary. It favors making the present state hospital into colonies for strictly chronic cases. It recommends that the first psychopathic hospital shall be established in Cook County. The commission urges that the study of psychiatry be made compulsory in all medical schools so that every person who enters the practice of medicine may have at least elementary knowledge regarding nervous and mental affections. A children's bureau, having broad power to deal with the dependent and delinquent classes, is also recommended by the commission.

---

[1] Stanford, R. V.: Vergleichende Studien über Cerebrospinalflüssigkeit bei Geisteskrankheiten, I. Dichte, Ztschr. f. physiol. Chem., 1913, lxxxvi, 43.

Chicago

New Hospital.—The Washington Boulevard Association is erecting a five-story building at Washington Boulevard and North Campbell Avenue to cost about $100,000. The building is to cover a ground area of 126x70 feet. Dr. Albert I. Bouffleur is chief surgeon of the association.

Personal.—Dr. Isaac C. Frisch, a member of the staff of the Chicago State Hospital, Dunning, has been transferred by the state to the Chester State Hospital, Menard, succeeding Dr. William H. Hercik.——Dr. and Mrs. T. J. O'Malley and Dr. Cornelius A. Leenheer have returned from abroad.

INDIANA

New Officers.—Thirteenth District Medical Society at Lake Wawasee, August 29: president, Dr. T. J. Shackelford; secretary-treasurer, Dr. C. Norman Howard (reelected), both of Warsaw.

Census of Centenarians.—Under the direction of the State Board of Health, a census and study of the centenarians of Indiana is to be made. Dr. J. N. Hurty, secretary of the State Board of Health, believes that such a study and investigation may be productive of value to the medical profession. Dr. Frank B. Wynn is associated with Dr. Hurty in the work and is preparing blank forms for use in making investigations and reports.

Tuberculosis Notes.—Dr. A. H. Caffee, Terre Haute, announces that the Twin Hills Tuberculosis Camp will close early in October on account of lack of funds. Next year it is hoped to keep the camp open through at least a part of the winter.——The Gibson County Society for the Study and Prevention of Tuberculosis has built a model tuberculosis-prevention sleeping house in the court house yard at Princeton.——A county sanatorium for tuberculosis is to be established at St. Joseph County at a point north of South Bend, and condemnation proceedings have been filed to obtain the thirty acres of land necessary for the project. The buildings will cost from $30,000 to $50,000, and will be grouped around a central administration building.

Personal.—Dr. George A. Sigler, Indianapolis, while crossing a street, was struck by an automobile, fracturing two ribs and one arm. He is said to be doing well at present.——Dr. Claude C. Crum, Jeffersonville, dislocated his right arm while cranking his automobile, August 30.——Drs. E. J. Lent, R. C. Shanklin, R. B. Dugdale, W. H. Baker and H. F. Mitchell, South Bend, and Dr. C. A. Dresch, Mishawaka, have started for Europe.——Dr. R. S. Rissler, Indianapolis, who has been in the government employ in Manila for more than four years, has returned to this country on leave of absence and will take a special course in sanitation at Harvard Medical School and in Vienna, before returning to his post of duty.——Dr. J. R. Mountain, Connersville, has returned from Europe.

Long State Hospital Almost Ready.—The Robert W. Long State Hospital, Indianapolis, connected with the Indiana University School of Medicine, is nearly completed and expects to be ready to receive patients about November 1. This building has been erected with funds amounting to $225,000, given by Dr. and Mrs. Robert W. Long, Indianapolis. The new hospital will be under the supervision of trustees of the university and directly under the care of the University School of Medicine. Dr. Edward L. Lingeman is to be medical resident in charge of the institution.——The additional units of the Indianapolis City Hospital are being rapidly completed and by the time they are ready to receive patients, on October 1, the hospitals will have a total capacity of about two-hundred and fifty.

IOWA

Personal.—Dr. Charles B. Burk, Atlantic, is reported to be seriously ill in Mercy Hospital, Council Bluffs.——Dr. Mark F. Boyd, health officer and city bacteriologist of Oskaloosa, has resigned to accept a fellowship in the department of preventive medicine and hygiene in Harvard University.——Dr. Merle F. Warner, Council Bluffs, is under treatment in the Jennie Edmundson Memorial Hospital for paralysis.

About Tuberculosis Camps.—The action of the Des Moines Associated Charities in abandoning Ridge Camp, an outdoor tuberculosis sanatorium in Highland Park, will result in the County Board of Supervisors erecting a building on the County Farm at a cost of $3,000 for the use of tuberculosis patients. The Ridge Camp was abandoned on account of the few patients remaining to be cared for, and for the time being, a temporary tent colony has been established at the County Farm.

Judges in Baby Contest.—The list of judges in the Baby Health Contest at the State Fair, Des Moines, include Dr. Lenna L. Meanes, Des Moines; Dr. Agnes Eichelberger, Sioux City; Dr. Velura E. Powell, Red Oak; Dr. Margaret V. Clark, Waterloo; Dr. Lucy M. B. Harbach, Des Moines; Dr. Jennie G. Ghrist, Ames; and Dr. Sophie H. Scott, Des Moines. Mrs. Mary Watt of Audubon, general superintendent of the contests, will be assisted by Dr. Florence B. Sherbon, Colfax, and Mrs. A. O. Ruste, Charles City.

KENTUCKY

New Officers.—Letcher County Medical Society reorganized at Whitesburg, August 29: president, Dr. Thomas A. Cook, Democrat; secretary-treasurer, Dr. Demsey F. Smith, Whitesburg.

Obstetrical Clinic Opened.—A free obstetrical clinic has been opened in the building of the Associated Charities, Louisville, every Wednesday afternoon, beginning September 3. The Babies' Milk Fund Association, the Visiting Nurses of the Kings' Daughters, the City Health Department, the University of Louisville and the Associated Charities, have united to operate the clinic of which Dr. Gavin Fulton is medical director.

State Association Meeting.—At the annual meeting of the Kentucky State Medical Association held in Bowling Green, September 2-4, the following officers were elected: president, elect Dr. James W. Ellis, Masonville; president, Dr. W. O. Roberts, Louisville; vice-presidents, Drs. James L. Neel, Drake; Marshall McDowell, Cynthiana, and James B. Kinnaird, Lancaster; secretary, Dr. Arthur T. McCormack, Bowling Green, reelected; treasurer, Dr. William B. McClure, Lexington (reelected); councilors, Dr. Dunning S. Wilson, Louisville, fifth district, and Dr. Joseph E. Wells, Cynthiana, eighth district; delegates to the American Medical Association, Drs. William W. Richmond, Clinton, and Archibald H. Barkley, Lexington; orator in medicine, Dr. William A. Poole, Henderson; and orator in surgery, Dr. A. D. Willmoth, Louisville. Newport was designated as the meeting place for 1914.

LOUISIANA

Free Treatment for Children.—The city health officer of Shreveport on August 23, issued a statement announcing that "all eye, ear, nose and throat specialists and dentists have agreed to treat all children free whose parents are unable to pay, and I am sure the general practitioners will do the same."

Personal.—Dr. W. W. Butterworth, New Orleans, has returned from Europe.——Dr. J. N. Thomas, superintendent of the Pineville State Hospital, who recently underwent operation at Touro Infirmary, New Orleans, is recuperating at Cooper's Wells, Miss.——Dr. J. A. White has been elected president of the reorganized Board of Health of Alexandria.——Dr. and Mrs. Rudolph Matas, New Orleans, are spending the summer abroad.——Dr. and Mrs. George F. Cocker have sailed for Europe.

MARYLAND

Sanatorium Completed.—The Allegany County Tuberculosis Sanatorium of Haystack Mountain near Cumberland, has been completed, and was thrown open to the public, September 4.

Personal.—Dr. C. L. Andrews, of Johns Hopkins University, has accepted the position of professor of anatomy in the University of Mississippi Medical College.——Dr. W. W. Wiley, Cumberland, is reported to be seriously ill at his home.

MICHIGAN

Campaign for Endowment Fund.—The trustees of the Detroit College of Medicine and Surgery, at the forty-fifth annual meeting, reported that more than $100,000 had already been secured in the campaign for the $1,000,000 for an endowment fund.

MINNESOTA

Charities Board Budget.—The Charities Board budget for Minneapolis for 1914 amounts to $357,140. Of this $205,000 is for the addition of 350 beds to the City Hospital; $50,000 for the Hopewell Hospital for Tuberculosis, and $34,318 for the acquisition of Lymanhurst, a home for children.

County Hospitals for Tuberculosis.—County hospitals for tuberculosis have already been completed in St. Louis and Ottertail counties.——The hospital for Ramsey county is under construction and the board of tax levy of Hennepin county has been asked to appropriate $50,000 for this purpose.——

Murray and Lyon counties will build a joint tuberculosis sanatorium at a cost of $12,000.——St. Louis County Tuberculosis Sanatorium, Nopeming, has passed the inspection of the State Tuberculosis Advisory Commission whereby it receives an appropriation of $25,000 from the state.

MISSISSIPPI

New Officers.—Seventh District Health Officers' Association at Brookhaven, August 28: president, Dr. C. E. Catchings, Woodville; secretary, Dr. D. W. Jones, Brookhaven.

Fire Losses.—The home of Dr. R. A. Switzer, McHenry, was destroyed by fire August 28.——The offices of Drs. William H. Hanson and J. G. Backstrom, Tutwiler, were destroyed by fire, recently, with a loss of about $3,000.

Biennial Report of Health Board.—Dr. W. S. Leathers, University, state health officer, in his biennial report, gives minute details regarding the hookworm campaign, showing that during the last two years more than one hundred thousand patients have been examined, and ninety thousand have been treated, free of charge. Of this number forty-five thousand were children, 60 per cent. of whom were found to be infected and were cured. During the biennium, 13,623 examinations were made in the State Board of Health laboratory.

Urge Medical Inspection.—At a meeting of the Committee of Public Policy and Legislation of the Mississippi State Medical Association, with the State Board of Health, to discuss health problems of vital importance, a resolution was passed recommending "that the cities of Jackson, Meridian, Natchez and Vicksburg establish medical inspection of the public schools in these cities at the earliest possible date and that this work be so organized as to demonstrate to the people of the state the need and economic advantages of school inspection."

MISSOURI

New Officers.—Wright County Medical Society organized at Mountain Grove, August 5: president, Dr. Robert M. Rogers, Mansfield; secretary-treasurer, Dr. Ernest J. Butzke, Mountain Grove.

Personal.—Dr. Milton J. Hopkins, St. Louis, sustained a fracture of three ribs and possible internal injuries in a collision between an automobile and a street car, September 1. ——Dr. William H. Winningham, Trenton, who underwent operation in the Henrotin Memorial Hospital, Chicago, recently, is reported to be doing well.

Sanatorium Fund Completed.—The Missouri Baptist Sanatorium, St. Louis, has secured the subscription of $50,000 required for this endowment fund which enables it to take advantage of the $100,000 from the estate of the late Alanson T. Brown. A new building will be erected at a cost of $150,000 adjoining the present structure and this will double the capacity of the hospital.

Systematic Free Nursing for Poor Consumptives.—So that every individual consumptive in St. Louis may have nursing care as well as medical attention, the St. Louis Society for the Relief and Prevention of Tuberculosis inaugurated a plan of district nursing, September 1. Under the new plan, each of the nurses of the society will be assigned a certain district of the city in which she will work. More than one hundred physicians of the city have volunteered their services in this good work.

NEW JERSEY

Personal.—Dr. M. I. Marshak has succeeded Dr. Joseph Adler as city physician of Bayonne.——Dr. Thomas C. McNamara, Hoboken, who has been seriously ill as the result of accidental poisoning by bichlorid of mercury, is reported to have recovered.

Non-Restraint Policy Adopted.—The superintendent of the State Hospital of New Jersey has reported to the governor the adoption of the method of non-restraint for insane patients, which has been carried on so successfully at the Peoria State Hospital under the direction of Dr. George A. Zeller.

Medical Staff Appointments.—The Stumpf Memorial Hospital Association, Kearney, announced the appointments of medical staff as follows: Dr. A. A. Strasser, Arlington, medical director; Drs. W. E. Doremus, Arlington; James R. Bramley, Arlington; Howard Dukes, Henry Allers, Harrison; E. S. Goudy, Kearney; W. B. Reick, Arlington; Marcus F. Squier, Arlington; Alfred A. Mutter, Arlington; John W. Reid, Kearny, and Walter G. Mead, Arlington. It is expected that the hospital will be opened early in October.

NEW YORK

Personal.—Dr. and Mrs. Amos T. Baker, Riverdale, have sailed for Europe.——Dr. C. M. Campbell, White Plains, has returned from Europe.

Growth of the Work Against Tuberculosis.—The progress made in the campaign against tuberculosis in the state is evidenced by the fact, that $630,500 has been given by individuals for the construction of hospitals for the care and cure of those afflicted with tuberculosis. Mrs. Elizabeth Newton, Fredonia, left $150,000 for a tuberculosis hospital; Mrs. Samuel W. Bowne, New York City, has given $100,000 for the construction of the Samuel W. Bowne Memorial Hospital; Alexander Smith Cochran, Yonkers, $250,000, for the Spraine Ridge Sanatorium for Incipient Cases and a site for the Municipal Hospital for Advanced Cases, valued at $8,000; B. B. O'Dell, Jr., Newbury, $25,000 for a tuberculosis hospital for Orange County; H. N. Adam, Buffalo, a site valued at $19,000, for a municipal tuberculosis sanatorium; anonymous donors, $60,000 for a tuberculosis division of the Albany Hospital; Mr. and Mrs. Charles E. Rayelyea, a site valued at $10,000 for the Elmira State Hospital; Robert H. Treaman, Ithaca, $5,500 for a site and part of the cost of the construction of the Tompkins County Tuberculosis Hospital; General H. W. Carpentier, Albany, 275 acres of land as a site and $2,000 toward the cost of the Saratoga County Hospital, and the late S. R. Bradley, Nyack, $1,000 to be applied to the Rockland County Tuberculosis Hospital.——Oswego County Tuberculosis Hospital, Orwell, erected at a cost of nearly $20,000, has been formally accepted by the board of supervisors. The institution is practically completed and will accommodate about thirty patients and is to be in charge of Dr. A. R. Allen, Orwell.

New York City

Travelers by Sea.—Dr. and Mrs. L. Faugeres Bishop, Dr. and Mrs. A. L. Smith, and Dr. Charles L. Dana, have recently arrived from Europe.——Dr. and Mrs. A. B. Berk have sailed for Panama.——Dr. and Mrs. L. Kast have returned from Europe.

Examiners of Defective Children Certified.—President Churchill of the New York Board of Education has received the following list of those certified as eligible for appointment as examiners of mentally defective children: Drs. Jacob T. Krause, Joseph G. Wilson, Harold W. Wright, Frank P. Jenks, Isabelle T. Lenart, Mary Appleton, Alice Leeder and Elsie Fox.

No Quarter for Cocain Users.—Five cocain users taken in a raid recently were sentenced to imprisonment for periods of from three to six months. One of the prisoners claimed that he used cocain because of suffering from tuberculosis of the spine but this brought him no clemency from the judge. One individual was sentenced to six months in the penitentiary for selling cocain to newsboys.

Lower City Death Rate.—The death rate for the week ended August 30 was 12.37 per 1,000 population, as against a rate of 13.28 for the corresponding week of last year. There was an increase in the number of deaths from measles, diphtheria, croup and whooping cough, but a decrease in the number of fatal cases of typhoid fever, there being but seven deaths due to this disease as compared with 19 for the corresponding week of 1912.

Personal.—Dr. Calvert M. DeForrest has been appointed deputy health officer of the Port of New York. Dr. DeForrest has just returned from Libau, Russia, where he has been in the Public Health Service for the last five years.——Dr. Howard C. Taylor was shot at by a disappointed or demented patient, August 22, but was uninjured.——Dr. T. L. Jones has accepted the position of surgeon to a mining and railroad hospital in Peru and sailed for his new post of duty, August 16.

NORTH DAKOTA

Good Work of State Sanatorium.—The State Tuberculosis Sanatorium, Dunseith, has so many applicants for admission that it has been necessary to erect a new cottage. The administration building is now being used for ward purposes for women, and male patients are being cared for in a cottage. The institution at present accommodates about fifty patients and the average weekly cost is $10.50 per patient.

Hospital News.—St. Joseph's Hospital is to be built at Minot by the Sisters of St. Francis at an approximate cost of $80,000. The building will be three stories in height, 200 by 42 feet, and will accommodate one hundred patients.——The new building of the State Hospital, Jamestown, is to be four stories in height, including a basement. It will be used as a ward building and will eventually be able to accommodate more patients by the construction of temporary wings at each end of the building.

OHIO

State Association Meeting.—The sixty-eighth annual meeting of the Ohio State Medical Association was held in Cedar Point, September 2-4, and the following officers were elected: president, Dr. George A. Fackler, Cincinnati; president-elect, Dr. John H. J. Upham, Columbus; secretary-treasurer, Dr. C. D. Selby, Toledo (reelected); chairman of the legislative committee and member of the legislative council, Dr. B. R. McClellan, Xenia; councilors, Drs. Clyde E. Ford, Cleveland, and Wells Teachnor, Columbus; delegates to the American Medical Association, Drs. Charles Graefe, Sandusky; W. D. Porter, Cincinnati; Charles L. Minor, Springfield; B. R. McClellan, Xenia; W. William Means, Columbus, and E. O. Smith, Cincinnati. Columbus was selected as the next place of meeting.

PENNSYLVANIA

Danville Hospital Cornerstone Laid.—With the grand officers of the Free and Accepted Masons in charge, the cornerstone of the $200,000 George F. Geisinger Memorial Hospital was laid in Danville, September 1. The hospital, a building to cost $200,000 and an endowment of $600,000, are given by Mrs. A. A. Geisinger, widow of the man for whom the new institution is named.

Philadelphia

Death of Wife of Dr. Montgomery.—Mrs. E. E. Montgomery died at her home, September 7, after a prolonged illness.

The Curtin Alumni Scholarship.—An appeal for funds has been issued by the Philadelphia Alumni Society of the medical department of the University of Pennsylvania to endow the scholarship intended to honor the memory of the late Dr. Roland G. Curtin. Remittances may be made to the treasurer of the fund, Dr. L. H. Adler, Jr., 1610 Arch Street.

Typhoid Fever.—Forty-seven new cases of typhoid fever developed in the city during the week ended September 6, a decrease of twenty-seven from the number reported to the Bureau of Health during the previous week. This is the least number recorded for any week since the first of August. Most of the cases are in the downtown and river wards and, according to Chief Vogleson, swimming in the Delaware and Schuylkill rivers is a source of infection. Analyses of the city water at the entrance to the mains from the filter plant have continued to show pure water, free from pollution, but analyses of water at the spigots in the river wards show pollution.

GENERAL

Roentgenologists Meeting.—The fourteenth annual meeting of the American Roentgen-Ray Society will be held in Boston, October 1-4. Lantern slide demonstrations will be an important feature of the proceedings and the plate exhibits promise to exceed all previous exhibits in size and illumination facilities.

More Hospitals for Cuba.—We learn from *Consular Reports*, August 7, that the cabinet of Cuba has granted the demand of the Department of Sanitation for forty new hospitals for the island. They are to be paid for from the lottery fund. A bill granting an appropriation of $65,000 for establishing a hospital at Guantanamo has also recently been signed by the president of the republic.

Hospital Officials Meet.—At the annual meeting of the American Hospital Association in Boston, August 28, the following officers were elected: president, Dr. Thomas Howell, New York City; vice-presidents, Dr. H. E. Webster, Montreal; Miss Mary A. Baker, Jacksonville, Fla., and Miss Mary Rogers, St. Louis; secretary, Dr. H. A. Boyce, Kingston, Ont., and treasurer, Mr. Asa Baker, Chicago (reelected).

Bequests and Donations.—The following bequests and donations have recently been announced:

Presbyterian Hospital, New York City, $5,000 by the will of Mrs. Jane Elizabeth Grannis, for the endowment of a bed in memory of her mother; St. John's Guild, $1,000, and Daisy Fields Memorial Hospital, $1,000.

St. Vincent's Hospital, New York City, $1,000 by the will of Elizabeth Varet.

German Hospital and St. Francis Hospital, New York City, each $5,000 by the will of Joseph Keder.

Military Surgeons to Meet.—The twenty-second annual meeting of the Association of Military Surgeons of the United States will be held in Denver, September 16-19, under the presidency of Surgeon William C. Braisted, U. S. N. An unique feature of the program is that one session of the association is to be held in a natural amphitheater at Red Rocks, Morrison, and another on the Continental Divide at Corona. The headquarters will be at the Brown Palace Hotel.

Meeting of Electrotherapeutists.—At the twenty-third annual meeting of the American Electrotherapeutic Association, held in New York City, September 2-4, the following officers were elected: president, Dr. George E. Pfahler; vice-presidents, Drs. Albert C. Geyser, New York City, Frank B. Granger, Boston; John W. Torbett, Marlin, Tex.; William L. Clark, Philadelphia, and Fred C. Tice, Roanoke, Va.; treasurer, Dr. Emil Heuel, New York City (reelected); secretary, Dr. J. Willard Travell, New York City (reelected), and lecturer, Dr. Fred M. Law, New York City (reelected).

Harvey Society.—The lectures of the Harvey Society for the coming winter include among others, Prof. A. D. Waller, London; Prof. Adolph Schmidt, Halle, Germany; Dr. Charles V. Chapin, Providence, R. I.; Dr. Rufus Cole, Rockefeller Institute; Prof. G. H. Parker, Harvard; Dr. Victor C. Vaughan, Ann Arbor, Mich.; Prof. Sven G. Hedin, Upsala, Sweden, and Prof. J. J. R. Macleod, Western Reserve University, Cleveland. The course will be inaugurated on October 4 by a demonstrative lecture by Dr. Waller, entitled "A Short Account of the Origin and Scope of Electrocardiography."

Colored Medical Men Meet.—At the fifteenth annual meeting of the National Medical Association, whose membership is composed of colored physicians, dentists and pharmacists, held in Nashville, August 26-28, the following officers were elected: president, Dr. A. M. Brown, Birmingham; vice-presidents, J. M. G. Ramsey, Richmond, Va., and O. La Branch, New Orleans; secretary, Dr. W. G. Alexander, Orange, N. J., (reelected) and treasurer, Dr. J. R. Levy, Florence, S. C. Officers elected for the medical section were Dr. J. R. Levy, Florence, S. C., president, and Dr. A. M. Tennant, Richmond, Va., secretary, and for the surgical section, Dr. N. L. Edwards, Bluefield, W. Va., president, and Dr. N. E. Cashin, Decatur, Ala., secretary.

Radium Apparatus Stolen.—Dr. F. L. de Verteuil, Royer's Building, Vancouver, B. C., writes that there was stolen from his office a few days ago, a radium apparatus. It was a flat, varnished apparatus from the Paris Radium Institute, 2½x3 cm., containing the equivalent of 60 milligrams of radium bromid of 500,000 activity. The apparatus was a silver disk on the back of which was the number "500." Filling the disk was the varnish, with the dissolved radium. The apparatus had been previously damaged and as the result the varnished surface was covered with small flakes of asbestos sticking to the varnish. A corner of the silver disk had a small dent in it. The apparatus was wrapped in several sheets of metallic lead, this being covered with black paper and rubber cloth over this. Should any reader of The Journal be offered a radium apparatus of the above description, Dr. de Verteuil requests that he may be notified at the earliest moment.

American Mine Safety Association.—An interesting program has been prepared for the meeting of the American Mine Safety Association at Pittsburgh, September 22-24, which was mentioned in The Journal of August 30. The meeting promises to be very largely attended. Prizes have been offered for men who compete in showing their skill in doing rescue work and recovery work at mines. Among the prizes are an oxygen inhalator and a miner's electric cap lamp, and medals for the individual contestants. A first-aid contest, similar to those held elsewhere in mining regions, is to take place and the prizes for this include first-aid cabinets and a first-aid instruction outfit and medals from the American Red Cross and American Mine Safety Association. An experimental explosion exhibit is to be given by the Bureau of Mines at their mine at Bruceton on September 23, which will enable those interested to see just exactly what caused the explosion, how the explosion acts, and the speed, pressure and other important items will be automatically recorded in the instrument room. A number of rescue men fitted with artificial breathing apparatus will enter the mine immediately after the explosion so as to illustrate how they can do rescue work in a mine while smoking and full of gas, immediately after disaster. On the evening of September 23 a smoker is to be given in the Fort Pitt Hotel to the visiting mining men.

Civil Service Examination for Chief Bacteriologist (Male).—The United States Civil Service Commission announces an open competitive examination for chief bacteriologist, for men only. From the register of eligibles resulting from this examination certification will be made to fill a vacancy in this position in the Bacteriological Laboratory of the Bureau of Chemistry, Department of Agriculture, Washington, D. C., at $3,500 a year, and vacancies as they may occur in positions requiring similar qualifications, unless it is found to be in the interest of the service to fill any vacancy by reinstatement, transfer or promotion. The duties of this position will be to direct all bacteriological and a portion of the fermentation work of the Bureau of Chemistry; to direct the work necessary in controlling the bacteriological purity of interstate shipments and importations of foods; to carry on all investigations of a bacteriological nature connected with the enforcement of the Food and Drugs Act, and to carry on other investigations connected with the agricultural chemical work carried on by the Bureau of Chemistry. Competitors will not be assembled for examination, but will be rated on general education and scientific training with 40 weights; practical experience and fitness with 30 weights, and publications along bacteriological and pathological lines with 30 weights. An educational training equivalent to that required for an M.D. or Ph.D. degree from a college or university of recognized standing, and at least seven years' practical experience in bacteriological and pathological work involving original investigations, since receiving such degree, are prerequisites for consideration for this position. Statements as to training, experience and fitness are accepted subject to verification. Applicants must have reached their thirtieth but not their fiftieth birthday on the date of the examination. Applicants for this examination must have been actually domiciled in the state or territory in which they reside for at least one year previous to the date of the examination. Recently the commission has obtained an appropriation whereby it is now able to have as examiners on various scientific, technical and professional subjects men who are recognized authorities in such subjects. In passing on the qualifications of candidates in this examination, the commission will have the assistance of an expert examiner who has been thus secured. This examination is open to all men who are citizens of the United States and who meet the requirements. Persons who meet the requirements and desire this examination should at once apply for Form 304 and special form to the United States Civil Service Commission, Washington, D. C.; the secretary of the Board of Examiners, Postoffice, Boston, Mass., Philadelphia, Pa., Atlanta, Ga., Cincinnati, Ohio, Chicago, Ill., St. Paul, Minn., Seattle, Wash., San Francisco, Cal.; Customhouse, New York, N. Y., New Orleans, La., Honolulu, Hawaii, Old Customhouse, St. Louis, Mo., or to the chairman of the Porto Rican Civil Service Commission, San Juan, P. R. No application will be accepted unless properly executed and filed with the commission at Washington with the material required, prior to the hour of closing business on October 6, 1913. In applying for this examination the title "United States Civil Service Examination for Chief Bacteriologist (Male)" should be used.

CANADA

Annual Report of Hospitals for the Insane, Ontario.—The total number of insane in the hospitals of Ontario is 5,726, of whom 2,769 are male and 2,957 female, an increase over the previous year of 86. The admissions for the past year numbered 1,247, an increase of 103. There were 460 deaths and 570 discharged. The deportations numbered 258, an increase of 32. Insanity in the province cost nearly $1,000,000 annually. Commencing with the cycle of five years, 1882 to 1886, the growth of insanity in Ontario has been as follows: 2,775, 3,201, 3,865, 4,604, 4,933, 5,517. Of the 1,247 admitted in one year, 890 inherited a predisposition.

Annual Meeting Ontario Medical Council.—At the recent annual meeting of the Ontario Medical Council Dr. M. O. Klotz, Ottawa, was elected president, and Dr. John L. Bray, 170 University Avenue, Toronto, was reelected registrar. The names of two practitioners were struck from the register. Sir James Grant, Ottawa, having attained to his forty-eighth year of membership of the council, was moved a hearty resolution of congratulations. A resolution was adopted instructing the registrar of the Ontario Medical Council to accept Dominion registration as full qualification for license in Ontario, subject only to the production of the necessary credentials and payment of the usual fee.

What Toronto Is Doing in Tuberculosis Nursing.—In the year 1911 the sanatorium accommodation for Toronto patients was 153; Island Preventorium, 25; dispensaries, three clinics a week with an average attendance of about six. In May, 1913, the sanatorium accommodation had reached 270; Island Preventorium, 50; Daughters of the Empire Preventorium, 10; Forest School, 100; dispensaries, six clinics a week with Department of Health nurses in charge with an average daily attendance of 15. Since this work was established in Toronto in 1911 in connection with the Department of Health, 2,272 cases have been recorded. Of these 97 had no medical supervision; 1,019 were at some time under the supervision of dispensaries and 1,156 were under the supervision of private physicians. In May, 1913, 281 physicians have reported 1,202 cases, with 102 duplicates. The classification is as follows: Advanced, 361; moderately advanced, 449; incipient, 283; not classified, 190; arrested, 21; reported for supervision, 893; no supervision necessary, 309; reported by physicians, 870; reported by dispensaries, 332. One hundred and thirty-five physicians who are known to have treated positive pulmonary cases have not yet reported one case; 868 cases have been reported first by nurses and others not qualified to make a diagnosis, and of these 131 have since been reported by physicians.

LONDON LETTER

(From Our Regular Correspondent)

London, Aug. 30, 1913.

The Prevalence and Preventability of Venereal Diseases

A report on this subject by Dr. R. W. Johnstone, a medical inspector of the Local Government Board, has been issued as a parliamentary paper. The deaths specifically registered as due to syphilis show a gradual and steady decrease from 89 per million in 1875 to 46 in 1910. It is considered doubtful, however, whether these figures are a reliable indication of the prevalence of the disease. Opinions collected from numerous specialists and physicians agree that there is as large or a larger proportion of syphilis as there was twenty years ago, but that the grosser lesions are less frequent than formerly. Moreover, there is no indication of a fall in the death-rates from disease caused by syphilis, such as locomotor ataxia, general paralysis of the insane, and aneurysm. On the other hand, army statistics show a remarkable diminution in the number of recruits rejected on account of syphilis, which has fallen from 158 per ten thousand in 1870 to 19 in 1911. Much syphilis is spread by infected males in consequence of ignorance or carelessness. The desire for concealment causes them to resort to quacks and pharmacists. Means for hospital treatment are defective. As a general rule no beds are reserved for venereal cases and lay managers often adopt the attitude that hospital funds should not be used to rescue patients from the consequences of sin. The report emphasizes the great advantage which would accrue if the necessary accommodations were provided in special wards in our general hospitals and free tests, such as the Wassermann, Noguchi, gonococcus and spirochete, were available. The time for making venereal disease notifiable is not considered to be ripe. The stigma attached to it is so great and the desire for concealment so marked that notification would prevent patients seeking medical advice.

Sir Jonathan Hutchinson's Will

Sir Jonathan Hutchinson left an estate of the value of $460,000, the bulk of which is divided among his eight children. He wrote the following directions in his will: "I desire to be buried in the same grave with my late beloved wife, the inscription on the gravestone to be, in addition to the names and dates, 'A Man of Hope and Forward-Looking Mind.'" He left his three museums, his clinical museum in London and his educational museums at Haselmere and Selby, to trustees to dispose of in their absolute discretion, but he stated his desire that they shall do so in accordance with his wishes expressed to them during his life.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, August 22, 1913.

Personal

Professor Bier and Professor Körte have been named as honorary members of the Royal College of Surgeons in London.

Professor Hering of Prague has accepted a position as dean of the newly organized institute for pathologic physiology in Cologne.

On August 26, Dr. W. A. Freund, formerly a well-known professor of gynecology at Strassburg, who has for the last ten years made his home in Berlin, celebrated his eightieth birthday.

Protection Against Cholera

In order to be forearmed so that Germany might not suffer through the bringing in of cholera from the Balkan countries, the German government has taken definite steps toward the prevention of such entrance. Thus the trains which come from the Balkan countries and Austria have been carefully searched for persons with signs of cholera. Since the great epidemic in Hamburg, through the teachings of Koch, cholera has been kept from Germany. We may hope that this time again she may be protected from such an epidemic. Two bacteriologists from Berlin, moreover, have been invited by the Servian government to the capital, in order to aid the physicians in making positive diagnosis.

Feeding of Schoolchildren

For the last five years needy children of the Berlin public schools have been fed through the use of a fund voted by the city magistrates. The importance of this step is shown by the facts, now published by a magistrate, that daily 1,300 children have had no breakfast and 7,000 have had no lunch at home. Each year a sum of from $25,000 to $50,000 has been voted for this purpose.

A Mesothorium Concert

The directors of the clinics and of the city hospitals have been endeavoring because of various publications concerning the favorable action of mesothorium on cancer, especially cancer of the uterus, to secure some of this preparation for clinical use. The state and various public officials and private committees as well have been endeavoring to raise money to buy a sufficient quantity of this preparation. In Munich at the initiative of Professor Döderlein, a concert was proposed, the proceeds of which should be used for this purpose. The prices paid by subscription for the tickets for this concert have been as much as $25. The various clubs and trade unions have promised their assistance so that there is hope that by means of the power of music, a sufficient quantity of mesothorium may be purchased.

Sanitary Conditions in the French and German Navies

In the last number of the *Deutsche militärärztliche Zeitschrift* an army surgeon presents comparative studies on the sanitary conditions in the French and German navies with especial reference to tuberculosis. He shows that the German marines are in better condition than the French as shown by the markedly lower annual morbidity and still lower mortality, and in the rarity of dismissal for unfitness for service on account of tuberculosis and suspected tuberculous disease. The physical inferiority of the French marines depends chiefly on the greater frequency of tuberculosis and is explained by the low standard of physical capacity required of recruits. This is chiefly due to the prevalence of tuberculous infection among the population along the French seacoast and also to the lack of adequate military reserves on account of the insufficient increase in the population.

Miscellany

Interstate Quarantine Regulations Regarding Water and Ice Supplied by Interstate Carriers.—The secretary of the treasury as authorized by Congress has amended the regulations in regard to the water and ice supplied by interstate carriers for the use of passengers in the following respects: The state or municipal health authority within whose jurisdiction water is obtained shall certify that it does not carry disease; in case of doubt the water must be treated so as to make it safe, and the treatment must be certified by the health officer. Ice for cooling water must also be certified to be safe, and if it is to be placed in the water it must first be washed carefully in water known to be safe and handled in such a way as to prevent it from becoming contaminated by the organisms of infectious or contagious diseases. To aid the common carriers in carrying out this regulation, instructions have been issued to the effect that samples of water and artificial ice from every source of supply shall be subjected to bacteriologic examination and certified as to purity at least once every six months by the proper state or municipal health authority where the water is obtained, or by such competent persons as will be approved by the health authorities, and the common carrier shall make application for the certificate. Each new crop of natural ice shall be examined and certified before use. Copies of the certificates are to go to the Public Health Service, to the common carrier and to the files of the issuing authority. Whenever there is an unusual prevalence of typhoid fever, dysentery, infantile diarrhea or other water-borne disease in any locality from which common carriers receive water and ice, an additional examination of the water and ice is to be made and a supplemental certificate issued by the proper authority. These regulations in regard to the safety of the drinking-water for the use of passengers on trains, vessels, etc., if carefully carried out, in connection with the abolition of the public drinking-cup, should do much to safeguard the public from dangerous diseases.

The Careless Liver and the Hygienist.—The average careless liver, although he may be perfectly willing to swallow some "magic" elixir, exhibits uneasiness tinged with suspicion when approached on the subject of prolonging his life by means of adjusting himself to his environment. He feels that the span of life is fixed, and he cherishes but little hope of "beating the game." In other words, that convenient individual, the "man on the street," is skeptical about materially prolonging his life without surrendering some of the indulgences which he thinks make life worth living. It is this attitude of mind which leads him frequently to characterize the health-reformer as a "kill-joy," who is "against everything." . . . But it is far from the minds of those directing this new force of human betterment to advocate a mere niggardly or parsimonious hoarding of existence, without regard to its quality, color or meaning. The real warfare is against needless misery, preventable disease, mental and physical inefficiency, and the pitiable handicaps that not only shorten life, but take out of it the color and the satisfaction that make it worth living. Using the term in no sinister Nietzschian sense, the superman should not only live long, but live well, deriving his joy in life from the normal hormones circulating in his tissues, and not from the fleshpots or narcotic indulgences of our friend, the careless liver. The prolongation of life is the end that justifies the means, and the immediate work in hand is to make life more livable.—Eugene L. Fisk, in *Pop. Sc. Monthly.*

Study of the Pathology of the Living.—When we consider the crushing disadvantages under which our forebears worked it is amazing to find how much they did, and with what accuracy they had solved many problems. The most conspicuous example of this extraordinary insight into abdominal diseases is, I think, afforded by the work of Brinton, whose books on "Diseases of the Stomach" and on "Ulcer of the Stomach" for wide observation, profound and cogent reasoning and beauty of language have never been challenged by those of any other writers. But with the new methods to which I have referred the study of the pathology of the living became possible. Symptoms recited at the moment could be ascribed to the lesion disclosed by the operation in the precise stage of its existence in which it was capable of arousing those symptoms. The history of abdominal surgery in the last ten years is the tale of the lessons that were learned.—Sir Berkeley Moynihan, Address in Surgery. Brit. Med. Assn., 1913.

Value of "Civic Health."—In our present enlightenment, men seeking homes and manufacturers casting about for the location of industries are more and more making healthfulness a prerequisite to their selection. A great industrial company, contemplating a change in location for their plant, sent a committee of intelligent workmen to inspect the town under consideration. The committee gave an adverse report because they were unable to ascertain anything which was definite in regard to the health of the place and because the statements of citizens were conflicting.—Birth and Death Bookkeeping, bulletin issued by Association of Life-Insurance Presidents.

Marriages

Narcisse Albert Laurendeau, M.D., St. Boniface, Man., to Miss Eva Brule of Fremont, N. Dak., at Walhalla, N. Dak., August 20.

William Earnshaw Styan, M.D., Quincy, Cal., to Miss Lottie Christine Gansner of San Francisco, August 16.

Warren Garfield Murray, M.D., to Miss Marion Louise Macfarlane, both of Kankakee, Ill., August 31.

John Pickens Cunningham, M.D., to Miss Beulah Thompson, both of Elbridge, Tenn., August 25.

Egerton T. Wilson, M.D., O'Neil, Neb., to Miss Harriett E. Hunt of Owosso, Mich., August 23.

Edward F. Duffy, M.D., Yonkers, N. Y., to Miss Margaret Ward of New York City, August 12.

William K. Farley, M.D., Fulton, Ill., to Miss Sarah Sturges, at Dixon, Ill., August 16.

Will Hawes, M.D., Fairbury, Neb., to Miss Alice Neville of Hebron, Neb., recently.

Edward J. Deibert, M.D., to Miss Flora Bader, both of Helerton, Pa., August 5.

Sofie Herzog, M.D., and Mr. M. Huntington, both of Brazoria, Tex., August 23.

Deaths

Harris Otis Perley, Colonel, M. C., U. S. A., retired, died at Fort Preble, Portland, Me., August 9, from kidney disease, aged 60. He was a graduate of Detroit Medical College in 1876 and in the same year entered the Medical Corps of the Army. Among his most important duties during the 36 years of his army service, were the command of the Army and Navy General Hospital, Hot Springs; the command of the hospital ship *Relief* in the Philippines and during the Boxer War; his detail as medical officer on the academic board of the United States Military Academy, West Point, and as chief surgeon of the departments of Mindianao and Colorado; Colonel Perley was retired May 8, 1913, on account of disability, incident to the service and since his retirement had lived in Portland, Me. He was a fellow of the American Medical Association and until a short time before his death a member of the Association of Military Surgeons of the United States.

Joseph Benson Marvin, M.D. Hospital College of Medicine, Louisville, Ky., 1875; a fellow of the American Medical Association; president of the Kentucky State Medical Association in 1894; president of the faculty and professor of principles and practice of medicine and clinical medicine in the University of Kentucky, Louisville; president of the medical staff of Norton Infirmary, neurologist to the Louisville City Hospital and physician to the Baptist Orphan Home; one of the most prominent practitioners of Kentucky; was killed in a collision between the Bar Harbor Express and the White Mountain Express on the New York, New Haven and Hartford Railroad, near New Haven, Conn., September 2, aged 61. His wife and daughter were traveling with him and both were killed.

James Owen Callahan, M.D. Missouri Medical College, St. Louis, 1888; a fellow of the American Medical Association; a member of the Southwestern Tri-State, Western District and Indian Territory Medical associations; for fifteen years chairman of the Creek Medical Examining Board and the author of the first and only medical laws ever passed by the Creek National Council; died at his home in Muskogee, Okla., August 29, from heart disease, aged 53.

Paul Gervais Robinson, M.D. Medical College of South Carolina, Charleston, 1856; surgeon in the Confederate service during the Civil War and since the close of the war a practitioner of St. Louis; for many years professor of principles and practice of medicine in Washington University and dean of the faculty of the Missouri Medical College; died at his home in St. Louis, August 22, from heart disease, aged 79.

Benjamin F. Miller, M.D. Medical College of Ohio, Cincinnati, 1859; assistant surgeon and surgeon of the Second Ohio Volunteer Infantry and brigade surgeon on the staff of General Scribner during the Civil War; once assistant professor of anatomy in the Ohio Miami Medical College and a member of the staff of the Cincinnati City Hospital; died at his home in Hyde Park, Cincinnati, August 23, aged 83.

Ira N. Barnes, M.D. Jefferson Medical College, 1862; a fellow of the American Medical Association and once president of the Decatur Medical Society; surgeon of volunteers during the Civil War; a member of the Illinois Army and Navy Medical Association; once a member of the Board of Health of Decatur, Ill.; died at his home, August 16, from cerebral hemorrhage, aged 84.

Thomas Robinson, M.D. Georgetown University, Washington, D. C., 1876; immediately after the Civil War the owner and editor of the *Savannah Journal*; for more than forty years an employé of the Treasury Department at Washington, and at one time president of the Board of Examiners of the Eclectic Medical Association; died at his home in Washington, August 25, aged 77.

Emerson Pullen McGeorge, M.D. Hahnemann Medical College, Philadelphia, 1894; a member of the Medical Society of the State of New Jersey; formerly coroner of Gloucester County and for two terms coroner of Salem County; died at his home in Woodstown, August 12, from the effects of a gunshot wound of the head, self-inflicted, it is believed with suicidal intent, aged 46.

Jane E. Spaulding, M.D. New York Medical College and Hospital for Women, 1861; formerly of Larned, Kan.; said to have been the third woman granted a certificate to practice medicine in the United States; for twenty years superintendent of the Santa Barbara (Cal.) Hospital; died at her home in Santa Barbara, August 31, from arteriosclerosis, aged 81.

Francis Asbury Emmons, M.D. Rush Medical College, 1863; Illinois Army Board, 1863; for many years a member of the Board of Education of Chicago, and at one time physician of Cook County; major and surgeon of volunteers during the Civil War and chief surgeon of Camp Douglas; died at his home in Chicago, August 21, aged 74.

Alphonso H. Madry, M.D. University of Louisville, Ky., 1886; a fellow of the American Medical Association and president of the Southwest Missouri Medical Society; local surgeon at Aurora, Mo., for the Kansas City, Fort Scott and Memphis Railroad; died at his home in Aurora, August 24, from disease of the lungs, aged 53.

Melbourne F. Middleton, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1868; for twenty years a member of the Camden (N. J.) Board of Health and one of the founders of the West Jersey Homeopathic Hospital; died at his home in Camden, August 21, from cerebral hemorrhage, aged 71.

Thomas Langan White, M.D. Jefferson Medical College, 1875; president of the McKeesport and Duquesne Bridge Company, the White Electric Traction Company, the McKeesport Light Company and the Chamber of Commerce of McKeesport; died at his home in that city, August 24, from pleuropneumonia, aged 60.

Daniel Manly Breaker, M.D. Oglethorpe Medical College, Savannah, Ga., 1861; a practitioner and minister of the Christian Church for more than fifty years, and a chaplain in the Confederate service throughout the Civil War; died at his home in Kissimmee, Fla., August 15, from senile debility, aged 82.

George Emory Foster, M.D. College of Physicians and Surgeons, New York City, 1868; at one time a member of the common council of Springfield, Mass., and for 43 years a practitioner of that city; died in Mount Clemens, Mich., August 22, a day after an operation for appendicitis, aged 63.

William A. Jordan, M.D. College of Physicians and Surgeons, Baltimore, 1873; one of the founders of St. Francis Hospital, Wichita, Kan., and later a member of the staff of the Wichita Hospital; for five years a physician of Sedgwick County; died at his home, August 19, from heart disease, aged 67.

Henry Gers, M.D. Miami Medical College, Cincinnati, 1880; a member of the Indiana State Medical Association; for several years a trustee of the School Board of Washington, Ind.; for two sessions a state senator; died in a hospital in Evansville, August 22, after a surgical operation, aged 68.

Mary Jane Laird, M.D. Woman's Medical College of the New York Infirmary for Women and Children, New York City, 1885; a pioneer physician of the San Joaquin Valley, Cal., and for many years a practitioner of Fresno; died at her home near Sanger, Cal., August 15, aged 67.

Joel E. Morrill, M.D. Northwestern Medical College of St. Joseph, Mo., 1884; for 36 years a practitioner of Chapman, Neb., and district surgeon for the Union Pacific System; since 1910 a resident of Lincoln, Neb.; died at his home, August 15, from cerebral hemorrhage, aged 73.

Robert Osborne Treadwell, M.D. Jefferson Medical College, 1846; is said to have been the oldest alumnus of Harvard University; for several years professor of languages in the University of Barcelona, Spain; died at his home in Portsmouth, N. H., August 23, aged 90.

Charles H. Zorger, M.D. Illinois Medical College, Chicago, 1897; a fellow of the American Medical Association; formerly a practitioner of Champaign and later a resident of Bloomington, Ill.; died at the home of his brother in Champaign, August 23, from nephritis, aged 46.

William Shuler, M.D. University of Pennsylvania, Philadelphia, 1867; a veteran of the Civil War; for 25 years a member of the Examining Board of Pensions and for two terms a member of the State Legislature; died at his home in Miamisburg, Ohio, August 11, aged 70.

William Wyatt Wiley, M.D. University of Maryland, Baltimore, 1871; local surgeon of the Baltimore and Ohio System at Cumberland, Md., for many years and formerly water commissioner of Cumberland; died at his home, August 26, from gangrene of the foot, aged 64.

Samuel Eldridge Ewing, Jr., M.D. Jefferson Medical College, 1902; at one time resident physician of the New Cape May Hotel; a member of the Medical Society of the State of New Jersey; died at his home in Tuckahoe, N. J., August 23, from acute gastritis, aged 35.

Homer Frank Parr, M.D. Medical College of Indiana, Indianapolis, 1903; a fellow of the American Medical Association; who went to New Mexico about eight years ago on account of ill health; died at his home in Carlsbad, August 18, from typhoid fever, aged 34.

Isaac Newton Boyd, M.D. College of Physicians and Surgeons, Baltimore, 1880; for seven years thereafter a teacher in the York Haven School and for twenty years a practitioner of Goldsboro, Pa.; died at his home, August 21, from heart disease, aged 60.

Abraham Iralson, M.D. Barnes Medical College, St. Louis, 1900; a fellow of the American Medical Association and a practitioner of Clifton Heights, St. Louis; died in the Deaconess Hospital in that city, August 2, from heart disease, aged 38.

David F. Penington, M.D. Maryland Medical College, Baltimore, 1885; for twenty years president of the Masonic Relief Association of Baltimore and a resident of that city until 1902; died at his home, August 16, from acute gastritis, aged 66.

Frederick Fenton, M.D. Trinity Medical College, Toronto, 1892; for many years a member of the gynecologic and obstetric faculty of the University of Toronto; died July 27, from peritonitis, following an operation for appendicitis, aged 42.

Everett E. Gordon, M.D. Homeopathic Medical College of Missouri, St. Louis, 1897; of Cairo, Ill.; was shot and killed by the son of a patient, at the entrance of the drive leading to St. Mary's Hospital, Cairo, September 1, aged 40.

John Reineking, M.D. Rush Medical College, 1887; Bellevue Hospital Medical College, 1888; a member of the Wisconsin State Medical Society; died at his home in Hortonsville, Wis., May 27, from carcinoma of the stomach.

Smith Rumble, M.D. Atlanta (Ga.) Medical College, 1887; a fellow of the American Medical Association and one of the leading practitioners of Pike County, Ga.; died at his home in Barnesville, August 20, aged 54.

William Henry McCarthy, M.D. College of Physicians and Surgeons, Baltimore, 1891; a member of the Massachusetts Medical Society; of Brockton; died in that city, about August 22, from appendicitis, aged 70.

James W. Bunn, M.D. Starling Medical College, Columbus, Ohio, 1873; a member of the Ohio State Medical Association and a veteran of the Civil War; died at his home in West Union, August 26, aged 71.

Thomas E. Stone, M.D. Tulane University, New Orleans, 1893; a member of the State Medical Association of Texas; died at his home in Jasper, August 18, from carcinoma of the throat, aged 53.

Samuel G. Bailey, M.D. Jefferson Medical College, 1844; for more than forty years a practitioner and banker of Chicago; died at his home in that city, June 20, aged 92.

John Alvin Leitch, M.D. Harvard Medical School, 1887; died at his home in Andover, Mass., August 26, from diabetes, nephritis and cerebral hemorrhage, aged 48.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

STANDARDIZING DISINFECTANTS

American Medicine Attacks the Hygienic Laboratory and the Council on Pharmacy and Chemistry

A report adopted by the Council on Pharmacy and Chemistry on "Standardization of Disinfectants," appeared in these columns April 26, 1913. The report was submitted by a committee appointed to consider the question of the recommendation of a method for standardizing disinfectants. The subject was gone into with thoroughness, the three leading methods—the Rideal-Walker, the *Lancet* and the Hygienic Laboratory methods—being carefully considered by the committee, which, as a result of its investigation, recommended to the Council the adoption of the Hygienic Laboratory method as described in the government publication, Hygienic Laboratory *Bulletin 82*.

After the publication of the Council's report, Mr. Walker, in a letter to *American Medicine*, defended his own method of standardization and protested against the report adopted by the Council. This was natural.

Of Mr. Walker's defense, we shall, at this time, have nothing to say. In the same issue of *American Medicine* which contains Mr. Walker's letter, however, that publication rushes to Mr. Walker's defense, editorially, and attacks, not merely the Council's report, but also the motives of the members of the Council on Pharmacy and Chemistry and, inferentially, of Dr. Anderson of the Hygienic Laboratory. That *American Medicine* should attack the Council is the most natural thing in the world; for the animus, one need look no further than its advertising pages. But its attack on the Hygienic Laboratory and its officers is different and aroused the indignation of the *Old Dominion Journal of Medicine and Surgery*, which, in its July issue, makes some comments that are worth quoting.

After stating that Mr. Walker, in his letter, makes no charges other than those which might naturally arise between disputants, the *Old Dominion Journal of Medicine and Surgery* goes on:

> "In commenting on Mr. Walker's letter, however, the editor of *American Medicine* takes an entirely different position, and makes statements and insinuations, which, if true, should receive prompt attention, and which, if untrue, should be as promptly withdrawn. Briefly, the editorial charges that the criticisms of the Rideal-Walker method have been dictated by a desire to promote 'a certain other test,' supposedly the Hygienic Laboratory method, and more serious still to 'further the use of a well-known antiseptic.' 'The situation is not a pleasant one to contemplate,' he states, 'for it suggests all too plainly reasons sordid and unsavory. Right always prevails, however, and we feel confident that when the true facts come to light Mr. Walker will find that the unpleasant experiences to which he has been subjected are simply the work of a few, who, instead of representing the great body of scientists of America, represent no one but themselves and their own selfish purposes.'
>
> "In considering this rather remarkable example of skating on the thin edge of libel, the facts should be kept carefully in mind. The scientific aspects of the question need no discussion at this time; the relative merit of the two methods is a matter capable of easy determination by a few months' practical application of both, and will doubtless settle itself promptly. In considering the alleged effort to discredit Mr. Walker and his method, and the discourtesies and difficulties he is said to have encountered, it should be remembered that since coming to America Mr. Walker has been in the employ of a manufacturer of disinfectants, and his status has been necessarily that of a hired advocate rather than that of a disinterested scientist. Whatever the conditions in England, we have come in America to accept the researches of scien-

tists connected with our universities and governmental agencies rather than those employed by private concerns. We shall doubtless continue to do so for some time to come.

"The charge that Mr. Walker's method has been discredited to boost the sale of a rival disinfectant is so serious as to warrant that some proof be promptly brought forward or else that the charge be withdrawn. Even here, however, we must take into account the fact that the publication in which the editorial appears carries a half-page advertisement of the very concern to which Mr. Walker sells his service.

"Those who know the officers of the Public Health Service, particularly Dr. Anderson, and who knew Dr. McClintic before he laid down his life to science, will pay but little heed to such charges until something more definite is forthcoming from some source whose disinterestedness can at least be presumed."

Summing up the whole matter, it resolves itself into this: *American Medicine* attacks, by inference, Dr. Anderson of the Hygienic Laboratory; further, it berates the Council on Pharmacy and Chemistry, a body which has had to expose the fraudulence of many, if not most, of the proprietary remedies from which *American Medicine* receives a large proportion of its advertising income; in addition, it exhibits a warmth of feeling in championing Mr. Walker and his method that may or may not be due to the fact that the concern which employs Mr. Walker and which manufactures and sells a disinfectant "standardized by the Rideal-Walker Test," is a purchaser of advertising space in *American Medicine*.

For a publication whose journalistic ethics rise no higher than the counting-house and whose editorial policy seems to be subservient to the advertising department; which exploits for a consideration—such proprietary frauds as Bannerman's consumption cure, Anasarcin, Phenol Sodique, Sal Hepatica, Cactina Pillets, Phenalgine, et al.; which publishes what seem to be editorial endorsements of some of the humbugs it advertises—for such a publication to attack, even by inference, the methods of such men as constitute the Council on Pharmacy and Chemistry and the Hygienic Laboratory, is to go beyond the limits of mere journalistic impertinence and to approach the realm of refined blackguardism.

DISEASE SUPERSTITIONS

As They Appear to Harper's Weekly

The belief is common among primitive and unlettered people that there is a specific remedy that will cure every disease of the body, if it can only be found.

Ignorant and superstitious people are peculiarly and pathetically susceptible to the persuasion of quacks who profess to have found the healing herb for their particular disease, and will go on squandering money and health after being defrauded a dozen times, because in their simple and pitiful faith they think each time, "Now, maybe, this man has found the real herb that will end my suffering."

This credulity is a matter for patient teaching. The health of the people is a national asset beyond the measure of dollars, but even the economic loss from avoidable sickness and death runs into unbelievable figures. The people must be carefully taught—not casually told—that disease is not an accident, not a dispensation of Providence or the infliction of an evil spirit, but the result of environment and of the mode of living. They must learn that health does not return by magic or by magic compounds; but it must be restored by a personal battle against disease.

Generous physicians, newspapers and journals, and social workers who are giving their time and means to fight the powers to prey and to spread the gospel of health, realize that education is slow. Thousands are saved every year, but it will take a long, strong effort to reach all the people with the truth. If ever there was an unselfish effort, and one of supreme importance to the country, it is the battle for national vitality.

What about the national health department at Washington?

—*Harper's Weekly*.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

QUESTIONS OF ETHICS

To the Editor:—Please answer the following questions:

1. Is it justifiable for a consultant to withdraw from the other physicians and hold a private conversation with a member of the patient's family?

2. Is a consultant ever justified in entering on a controversy with the attendant in the presence of the patient?

3. When the consultant takes charge of a patient because of a difference of opinion that he holds from that of the attending physician, is it proper for him to ask the physician whether or not the latter has relinquished the care of the patient? If this question is asked should it be in the presence of a third party, a layman?

X. Y. Z., South Carolina.

Answer.—In answering these questions it must be remembered that our reply is a general one. In any particular case both sides to the dispute should be heard before judgment is announced.

1. "In every consultation, the benefit to be derived by the patient is of first importance. All physicians interested in the case should be frank and candid with the patient and his family. There never is occasion for insincerity, rivalry or envy and these should never be permitted between consultants" ("Principles of Medical Ethics," Sec. 2, Art. III, Chap. II). While it is best that all consultants avoid "private conversations" with members of the patient's family during the consultation, the relations of one of the physicians with some of the friends of the patient may make such a talk unavoidable. Should the physician have the least suspicion that he does not have the absolute confidence of the others interested in the case, he will do well casually to report his interview and state the nature of such discussion during the conference of the consultants.

2. "Should the attending physician and the consultant find it impossible to agree in their views of a case, another consultant should be called to the conference or the first consultant should withdraw. Since, however, the consultant was employed by the patient in order that his opinion might be obtained, he should be permitted to state the result of his study of the case to the patient, or his next friend, in the presence of the physician in charge" ("Principles of Medical Ethics," Sec. 7, Art. III, Chap II). This statement of opinion can and should be made without controversy.

3. "When a physician has attended a case as a consultant, he should not become the attendant during that illness except with the consent of the physician who was in charge at the time of the consultation" ("Principles of Medical Ethics," Sec. 8, Art. III, Chap. II). It is the office of the patient, or his next friend, to obtain the necessary consent of the physician who was in charge at the time of the consultation.

RECURRENCE OF GALL-STONE AFTER OPERATION

To the Editor: Are there any authentic cases of recurrence of gall-stones following a thorough operation for their removal? If so, kindly give references.

E. C. R.

Answer.—The question of recurrence of gall-stones after their removal by surgical operations is one which operators have found difficult to decide, because it is impossible in the majority of cases to be absolutely certain that stones found in the second operation were not overlooked in the former one. It is probably quite common for stones to be missed in an operation, which subsequently give rise to trouble.

For instance: Kehr states that in nineteen out of 491 gall-stone operations, or 4 per cent. of the cases, he overlooked or left in one or more stones. Shott states that in 260 gall-stone operations stones were overlooked twenty-eight times, or 10 per cent. of the cases. These twenty-eight cases appeared to be examples of recurrence, but Shott on analysis (*Beitr. z. klin. Chir.*, xxxix) thinks that in probably all of them the stone or stones which were found at a subsequent operation or at the necropsy were present at the first operation and overlooked. Kehr, however, reports that at a secondary operation he found a stone in the center of which was a small piece of catgut which had been used for sewing the gall-tracts at the first operation. This would certainly exclude the possibility of this stone having been overlooked.

Gall-stones, as a rule, undoubtedly have their origin in the gall-bladder. If the gall-stones were removed and the gall-bladder restored to a reasonably normal condition, it is perfectly conceivable that the conditions which gave rise to the stones in the first instance might readily produce stones a second time, should the conditions recur. As a matter of fact, the conditions leading to the formation of gall-stones seem to occur at a particular time, and experience shows that these conditions very seldom recur. Hence it is exceedingly rare for a recurrence in the sense of the actual formation of new stones *de novo*, after their removal by surgical operation.

AUTOGENOUS VACCINES IN PYORRHEA ALVEOLARIS

To the Editor:—Please give me an opinion as to the merits of autogenous vaccines in the treatment of pyorrhea alveolaris.

L. C. Greenburg, Indianapolis.

Answer.—The treatment of pyorrhea alveolaris with vaccines has been taken up only recently, and as yet a sufficient number of cases has not been reported to justify any conclusion. Indeed, the bacteriology has not been sufficiently studied so that autogenous vaccines of any definite organism have been used in more than a few cases. In general, reports on this subject have included only from three to ten cases in all, with results usually favorable. The organisms most commonly used have been the various streptococci, staphylococci and the pneumococci. In view of these facts, no exact statement can be given at this time. The following references concern some of the better reports:

Eyre, J. W., and Payne, J. Lewis: Some Observations on the Bacteriology of Pyorrhea Alveolaris and the Treatment of the Disease by Bacterial Vaccines, *Proc. Roy. Soc. Med.*, Odont. Sec., Nov. 22, 1909.

THE "FOGGING SYSTEM" IN REFRACTION WORK

To the Editor:—Please explain the "fogging system" in examining the eyes.

L. L. E., Iowa.

Answer.—The fogging system means the overcorrection of hyperopia in cases of persistent spasm of the ciliary muscle in which the end sought is a certain degree of functional activity rather than complete immobility. The method simulates the static or cycloplegic method as the ciliary muscle is partially placed at rest by having in front of the eye examined a plus sphere of sufficient strength to more than overcome any ciliary muscle power that the eye might otherwise use when looking at a distance of 20 feet. It is called the fogging method because distant vision is made obscure or foggy by the overcorrecting lens, which renders the eye to all intents and purposes myopic while the lens is being used. This point should be kept in mind in estimating the refractive error, and one should proceed as in any regular case of refraction for myopia. It is only occasionally of service in eyes that have some form of hyperopia or simple myopic astigmatism, but it is not of service in myopia or compound myopia. It might be used in the young subject who must be refracted without drops on account of some local or constitutional disease, but it is not to be relied on as is refraction under a cycloplegic with the added assistance of the skiascope. It is not advisable to use this method without knowledge of the ophthalmoscopic findings, as it often leads to gross errors or even to injury to the eyes.

PHYSICAL CONSTANTS OF OIL OF HORSE CHESTNUT—DETERMINATION OF EPINEPHRIN

To the Editor:—1. Please give the physical constants of oil of horse chestnut (*Aesculus hippocastanum* L.). 2. Also a method for the quantitative estimation of epinephrin chlorid.

Morris T. Myers, Norman, Okla.

Answer.—1. Stillesen (*Proc. Am. Pharm. Assn.*, 1909, lvii, 201) has examined the fixed oil of horse chestnuts, which he obtained from the dried fruits in a yield of from 1.5 to 3 per cent. The oil contains traces of a mustard-like volatile oil which, however, could not be isolated. The specific gravity at 15 C. was 0.9260; refraction index at 20 C., 1.4747; saponification number, 194.5; iodin number, 95.4; Reichert-Meissl number, 1.54; Hehner number, 92.9; acetyl number, 13.5. The oil is mainly composed of olein, containing besides small quantities of linolein, palmitin and stearin. Sulphur was not present. It is intermediate between the half-drying and non-drying oils.

2. A biologic method for the valuation of epinephrin preparations has been elaborated by the Council on Pharmacy and Chemistry and appeared in The Journal, Sept. 30, 1911, p. 1149. Chemical (colorimetric) methods for the determination of epinephrin have recently been published by Otto Folin and his coworkers (*Jour. Biol. Chem.*, 1913, xiii, 477), and by Atherton Seidel (*Ibid.*, 1913, xv, 197).

USE OF DIPHTHERIA ANTITOXIN AS AN IMMUNIZING AGENT

To the Editor:—Please tell me whether or not diphtheria antitoxin has been discontinued as an immunizing agent, and if there is any literature to the effect that if given as an immunizing agent and the patient should subsequently develop diphtheria, it would be hazardous to administer antitoxin.

T. F. H., M.D., Anniston, Ala.

Answer.—A partial answer to this question was given in The Journal, Jan. 11, 1913, p. 147. Diphtheria antitoxin is quite generally used as an immunizing agent. Usually a dose of 500 units is given to all the children in a family in which a case of diphtheria has developed. In such instances no attention is paid to the possibility of anaphylaxis on later injection of diphtheria antitoxin. Indiscriminate immunization by the injection of serum is not advised by any of the writers on this subject. To avoid serious results from anaphylaxis in cases in which known immunizing doses have previously been given, it is customary to inject first a small dose of from 5 to 8 minims, and if no symptoms develop, to follow this within an hour with the full dose which it is desired to inject.

TREATMENT OF XEROSTOMA

To the Editor:—I have a patient whose mouth and pharynx are perfectly dry at all times. The mucosa of the lips, cheeks, soft and hard palate, fauces, pharynx and larynx is perfectly dry and glazed and there does not seem to be any secretion of mucus. This condition has existed for four years. What could cause such a condition? She has some heart-muscle weakness, but kidneys and rest of body are all right. There is a faint yellow tinge to the conjunctiva. Please let me know what you think could cause such a dry condition of the mucosa.

C. T. Pankhurst, M.D., North Star, Mich.

Answer.—Xerostoma or dryness of the mouth is attributed to an affection of the nerve supply of the glands of the mouth. It usually occurs in females and it may be due to febrile conditions, mouth breathing, diabetes, etc. The systemic condition should be carefully determined and appropriate remedies given. Small doses of potassium iodid and pilocarpin (0.003 gm. or 1/20 grain) allowed to dissolve in the mouth with a little water are useful. Galvanism is recommended in cases of centric origin.

THE CONSUMPTION OF SUGAR

To the Editor:—Will you kindly inform me whether 82 pounds per capita (as in "Sugar as Food," editorial, The Journal, Aug. 16, 1913, p. 492) is correct?

H. E. Mereness, M.D., Albany, N. Y.

Answer.—According to Senate Document 890, Sixty-Second Congress, the annual per capita consumption of sugar in the United States is given as 79.2 pounds. Of this amount 53.7 pounds, or 268.5 pounds per family, is purchased by consumers for direct consumption as determined by the U. S. Bureau of Labor of 1901. The remaining 25.5 pounds is purchased by manufacturers for use in confectionery, condensed milk, biscuits, chewing-gum, and other manufactured products.

EFFECTS OF CALCIUM LACTATE

To the Editor:—Please tell me if there would be any untoward effects from the use of calcium lactate given in doses of from 45 to 60 grains a day continued over a very long period of time.

A. C. England, M.D., Pittsfield, Mass.

Answer.—Probably not. It is somewhat doubtful whether calcium salts are absorbed to any large extent from the gastro-intestinal tract.

VIOLET RAYS AND STERILITY

To the Editor:—Can you inform me whether or not there is any truth in the statement that violet rays and high-frequency applications cause sterility, the same as Roentgen rays?

C. L. H. Schwartz, New York, N. Y.

Answer.—We find no references to such an action in recent current medical literature, and the text-books on medical electricity give no evidence of such a fact.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARIZONA: Phoenix, October 7-8. Sec., Dr. John Wix Thomas, Phoenix.

COLORADO: State Capitol, Denver, October 7. Sec., Dr. David A. Strickler, 612 Empire Building.

GEORGIA: Regular, State Capitol, Atlanta, October 14. Sec. Dr. C. T. Nolan, Marietta; Homeopathic, Atlanta, October 1. Sec., Dr. R. E. Hinman, 106½ Whitehall St.; Eclectic, State Capitol, Atlanta, October 14. Sec., Dr. C. W. Miller, 192 W. North Ave.

IDAHO: Boise, October 7. Sec., Dr. John F. Schmershall, Jerome.

ILLINOIS: Coliseum Annex, Chicago, September 24-26. Acting Sec., Amos Sawyer, Springfield.

KANSAS: National Hotel, Topeka, October 14. Sec., Dr. H. A. Dykes, Lebanon.

LOUISIANA: New Orleans, October 27-29. Sec., Dr. A. B. Brown, 34 Cusachs Building.

MICHIGAN: Capitol Bldg., Lansing, October 14-16. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

MINNESOTA: University of Minnesota, Minneapolis, October 7-10. Sec., Dr. Thomas S. McDavitt, 814 Lowry Building, St. Paul.

MISSISSIPPI: Jackson, October 28-29. Sec., Dr. E. H. Galloway, Jackson.

MONTANA: State Capitol, Helena, October 7. Sec., Dr. Wm. C. Riddell, Helena.

NEW JERSEY: State House, Trenton, October 21-22. Sec., Dr. H. G. Norton, 429 E. State Street.

NEW MEXICO: Santa Fe, October 13. Sec., Dr. W. E. Kaser, East Las Vegas.

NEW YORK: September 23-26. Chief of Examinations Division, Mr. Harlan H. Horner, Department of Education, Albany.

OKLAHOMA: Muskogee, October 14. Sec., Dr. John W. Duke, Guthrie.

RHODE ISLAND: State House, Providence, October 2-3. Sec., Dr. Gardner T. Swarts.

UTAH: Salt Lake City, October 6-7. Sec., Dr. G. F. Harding, 310 Templeton Building.

WYOMING: State House, Cheyenne, October 15. Sec., Dr. J. B. Tyrrell, Laramie.

New Jersey Reciprocity Report

Dr. H. G. Norton, secretary of the New Jersey State Board of Medical Examiners, reports that sixty-one candidates were licensed through reciprocity since Jan. 1, 1913. The following colleges were represented:

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
University of Colorado	(1907)	Utah
College of Physicians and Surgeons, Chicago (1904)	(1907)	Illinois
University of Iowa, College of Medicine	(1892)	New York
Baltimore Univ... (1903) Pennsylvania (1898)	(1900)	New York
Boston University	(1905)	Maine
New York Univ. Med. Coll. (1898) New York;	(1898)	Penna.
Eclectic Med. Coll., New York...(1899) (1900)	(1906)	New York
New York Homeo. Med. Coll. and Hosp	(1911)	New York
Albany Medical College	(1903)	New York
Syracuse University	(1912)	New York
Cornell University (1903) (1905)	(1911)	New York
University and Bellevue Hospital Medical College, New York (1908) (1911) New York.		
Columbia University, College of Phys. and Surgs. (1898) (1904) 1907, 2) (1910, 2) (1911) (1912, 2) New York.		
Long Island College Hospital, New York (1900) (1908) (1909) New York; (1912) District of Columbia.		
University of Pennsylvania (1898) (1899, 2) (1911) (1912) Pennsylvania.		
Jefferson Medical College (1910) Maine; (1898) (1900) (1910) (1912) Pennsylvania.		
Hahnemann Medical College and Hospital, Philadelphia (1894) (1897) (1902) (1910) Pennsylvania.		
Women's Medical College of Pennsylvania (1901) New York; (1912) Pennsylvania.		
Medico-Chirurgical College of Philadelphia (1906, 2) (1909) (1912) Pennsylvania.		
University of Pittsburgh	(1909)	Penna.
University of *Vermont*	(1912)	Vermont
University of Naples, Italy (1895, 2)	(1896)	New York
University of Palermo, Italy	(1887)	New York

Kansas February Report

Dr. H. A. Dykes, secretary of the Kansas Board of Medical Registration and Examination, reports the written examination held at Topeka, Feb. 11-13, 1913. The number of subjects examined in was 10; total number of questions asked, 100; percentage required to pass, 75. The total number of candidates examined was 4, of whom 3 passed and 1 failed. Fifteen candidates were licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Howard University, Washington, D. C.	(1912)	82.
University of Kansas	(1912)	81
Kansas City Medical College	(1903)	76.
FAILED		
Meharry Medical College	(1911)	66

LICENSED THROUGH RECIPROCITY

College	Year Grad.	Reciprocity with
Northwestern University Medical School	(1905)	Iowa
Hering Medical College	(1902)	Colorado
Eclectic Medical College of Indiana	(1904)	Texas
Medical College of Indiana	(1894)	Indiana
Iowa College of Physicians and Surgeons, Des Moines,	(1896)	Iowa
University of Louisville	(1912)	Kentucky
St. Louis University	(1909)	Missouri
Washington University, St. Louis	(1910)	Missouri
University Medical College, Kansas City	(1898)	Missouri
Eclectic Medical College, Cincinnati	(1911)	Missouri
University of Tennessee (1906)	(1912)	Tennessee
College of Physicians and Surgeons, Memphis	(1911)	Tennessee
Tennessee Medical College	(1894)	Tennessee
Meharry Medical College	(1912)	Tennessee

Massachusetts May Report

Dr. W. P. Bowers, secretary of the Massachusetts Board of Registration in Medicine, reports the written and practical examination held at Boston, May 13-15. The number of subjects examined in was 13; total number of questions asked, 70; percentage required to pass, 75. The total number of candidates examined was 41, including 12 non-graduates and 5 osteopaths, of whom 21 passed, including 4 non-graduates and 1 osteopath, and 20 failed, including 9 non-graduates and 4 osteopaths. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Bennett Medical College	(1913)	80
Chicago College of Medicine and Surgery	(1912)	75
Medical School of Maine	(1899)	81

Patent Medicine Domination.—The way out of the "patent-medicine" domination lies in the better training of physicians on the one hand and the enlightenment of public opinion on the other. No more effective agency exists for the forming of public opinion than an aggressive administration of the bureau at Washington which deals with pure food and pure drugs. No single agency in this direction has counted for so much as the personal work of one man, who has spent his life in fighting frauds and poisons. But we must have a hundred Wileys in the public service where now we have not one.—David Starr Jordan, *Science.*

Book Notices

The American Encyclopedia and Dictionary of Ophthalmology. Edited by Casey A. Wood, M.D., C.M., D.C.L. Volume I: A to Azoviolett. Cloth. Price, $6. Pp. 727, with illustrations. Chicago: Cleveland Press, 1913.

Of making books there is no end; but, till this ambitious volume, there had never been even a beginning of any attempt at a comprehensive, truly exhaustive exposition of ophthalmology in English. Text-books indeed have appeared in English from time to time, some of much, and more of little, worth. Quiz-compends have been known to exist. Numerous periodicals have been published—annals, journals, archives, records, etc.—and these, in general, have held their own with similar publications in German, Italian and French. Then, finally, appeared the Norris and Oliver "System of Diseases of the Eye," in four quarto volumes, extremely useful even now. But even that systematic treatise exhibited lacunae. It told us, for example, much of ophthalmology, but nothing at all of ophthalmologists. It showed, in a highly commendable manner, the ophthalmic practice of the day in which it appeared, but nothing whatever of the earlier stages of this slowly developing art—it exhibited, in other words, all the modern flower and fruitage, but absolutely nothing of the rough medieval trunk, or of the strong *ancient* roots, which, for sustenance, dipped far down into a humus of philosophy and religion. Then, too, in matters of refraction and accommodation, in ocular innervation and motility, as well as in a thousand lesser matters, like the accommodometer, the angulometer, the Aleppo button, and ophthalmologic chemistry and botany, the "System" of Norris and Oliver was most decidedly defective.

The French have done better. They have their "Encyclopédie française d'ophthalmologie"—nine goodly volumes that cover the major portion of the subject of ophthalmology, though omitting a number of extremely important matters.

The Germans have done better still. They produced, as a kind of beginning, the first edition of the Graefe-Saemisch "Handbuch der gesammten Augenheilkunde"—not so much a handbook, by the way, as a heavy, double armload of very extensive treatises. Then, patiently, and after the fashion of the great Teutonic investigators and writers—a fashion which will sooner or later be followed in this land of too many short-cuts—the Graefe-Saemisch editors and contributors set to work on a *monumental* "Zweite Auflage"—an enormous production which is still in the course of publication. Unfortunately, however, so extensive and so unrelated are the numerous parts of the "Zweite Auflage" that the reader has great difficulty in finding anything in it, and will continue to have until the work is complete and furnished with an index.

There was also a German Encyclopedia of Ophthalmology—excellent, too, but ill-starred. It went to about the letter M, since which nothing has appeared.

This is the first volume of an American attempt of similar character—an attempt which, we believe, is also the first of its kind in the English language.

The work is planned to appear in *ten octavo* volumes, each of seven or eight, or possibly *nine*, hundred pages, and then, at the close, an appendical volume, in which will be comprised, chiefly, such discoveries of importance in the field of ophthalmology as happen to have been made too late to be included in any of the earlier volumes.

The volume now before us—a well-bound, well-printed, beautifully illustrated production—is devoted entirely to subjects that begin with the letter A, and the comprehensive character of the work as a whole is well shown by the opening article of this the opening volume—"A": "Just as in modern times one often uses the initial letter of the name of a patient whose identity one desires to conceal, so the ancients occasionally employed the same device." The article thus begins and then goes on to relate the anamnesis and case report of an ophthalmic patient dead more than twenty hundred years. But the case is illustrative of ancient ophthalmic temple-practice, and so it is admitted to the book. The final article in the volume is entitled "Azoviolett," the name of a certain tint used now and then in spectacle lenses.

Between these two articles lie hundreds of others, varying, of course, in value, but, for the most part, scholarly, and so clearly, often so picturesquely, written as to be of the utmost interest alike to specialists and general practitioners. Among the contributors to the volume are Jackson, Allport, Frank, Würdemann, Ball, Beard, Rochester, Zentmayer, Gradle, Shastid, Posey, McKee and, indeed, nearly all the other men who have made American ophthalmology what it is. None but American (including, of course, Canadian) ophthalmologists contribute to the volume or to the series.

Aside from his work as one of the contributors, Dr. Wood is to be cordially congratulated—still more, the world of ophthalmology—on the masterly editing exhibited throughout the volume. The fine coordination of article with article, in works of an encyclopedic character, is never the result of happy accident.

Whether or not the standard erected by Volume I of this Encyclopedia is to be attained by succeeding volumes, the *initial effort* of the series will indubitably stand as a credit to American scholarship and American literary style. There should be more works of a similar character devoted to other specialties.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By Various Writers. Third Edition. Edited by Thomas Lathrop Stedman, A.M., M.D. Complete in 8 Volumes. Cloth. Price, $56 set. Volume I—Aachen to Bacteriuria. Pp. 928, with 611 illustrations. New York: William Wood & Co., 1913.

This work, which has been favorably received by two generations of medical men and is now before us in its third edition, is essentially a new one. The first two editions were edited by Dr. Albert H. Buck, but the third appears under the supervision of Dr. T. L. Stedman. It is not necessary to compare the previous editions with the present one, as it is evident that such a comparison could only illustrate the well-known fact of the tremendous advance of medicine in the past decade. Not only have the articles dealing with subjects treated in the second edition been thoroughly revised, but more or less extended treatises on new subjects have been added. Some characteristics of the work shown by a perusal of the first volume are worthy of notice. The first feature is the variety of the material and the number of authors who have been secured to present it. The list of contributors includes over a hundred names of specialists, most of whom are well-known American authors. The variety of subjects is still more striking; the larger topics are presented under convenient alphabetical subdivisions so that the anatomy of the abdomen forms a special topic in its alphabetic order. In addition a system of cross-references enables one to find the description of minor topics. Under these cross-references are included in many cases a sufficient account so that the larger title need not be referred to. The scope of the work includes medical history and biography, so that one may seek information here that he will fail to find in other systematic works. The extension of the work in the direction of the fundamental sciences, such as chemistry, biology, anthropology, etc., affords a welcome fund of information to one who has not the most extensive general encyclopedias at hand. Especially the information in reference to climatology and the conditions at various resorts and health stations would be difficult to duplicate. The thorough treatment of the individual topics can be appreciated only by careful reading. The subject of bacteria and bacteriologic technic is given over a hundred pages of this large volume, easily equivalent to three hundred of the ordinary text.

Another feature that adds materially to the value of the work is the excellent illustrations. Many are in colors, and especially those of skin diseases and of pathologic changes depict very strikingly and faithfully the objects described.

A review of the subjects included in the first volume is impossible in the space at command. The first important topic is the surgical anatomy of the abdomen, and this is supplemented by the surgical anatomy of the abdominal organs and a consideration of the diagnosis of abdominal tumors. These articles furnish a thorough account of a very important subject. We note that the illustration of the position of the organs pictures the stomach as lying transversely across the abdomen, following the anatomic text-books of a past decade. Another unimportant but very noticeable adherence to an older view is the statement that the colon is to be inflated by passing a tube into the descending colon, an unnecessary and probably impossible performance. On the whole, the treatment of these subjects seems very satisfactory. We shall await the appearance of the subsequent volumes of the series with great interest. If, as is to be assumed, they bear out the promise given by the initial volume, we can predict that these volumes will be as indispensable to the next generation of medical men as their predecessors have been to the present.

Text-Book of General Pathology. By Various Authors. Edited by M. S. Pembrey and J. Ritchie. Cloth. Price, $5 net. Pp. 773, with 40 illustrations. New York: Longmans, Green & Co., 1913.

The subject of this work is not morbid anatomy but morbid physiology, whose "province is to correlate the processes in the diseased with those in the healthy; to determine the causes of failure in the interdependence of the different parts of the body; to show how the failure of one tissue reacts on all other tissues, and by following the progress of disease to explain how it causes death."

The book is the work of a number of specialists, including physiologists, pathologists and clinicians. The editors expressly state that no attempt has been made to reconcile divergencies of opinion which may appear in the different sections. The work is intended for advanced students and general practitioners. It is devoted to the consideration of a class of topics which must appeal to both classes from their intrinsic interest as well as their practical importance.

General Surgery. Edited by John B. Murphy, A.M., M.D., L.L.D. (Practical Medicine Series, Vol. II.) Cloth. Price, $2. Pp. 632, with 252 illustrations. Chicago: The Year Book Publishers, 1913.

The subjects taken up particularly in this volume are anesthesia, operative technic, wound-healing and pathologic interventions, malignant tumors, surgery of bones, joints, tendons, blood-vessels, skull and brain, face and mouth, thyroid, thymus, thorax, abdomen, appendicitis and fractures. The book is well illustrated, and of special value to the reader, aside from the good selection of the material, are the comments of the editor. His wide experience and unusual acuity of clinical observation naturally have led him to formulate opinions which cannot fail to be of value to every practitioner. The book contains a great deal of practical, useful material such as the general surgeon needs to refer to daily.

Blood-Pressure in General Practice. By Percival Nicholson, M.D. Cloth. Price, $1.50. Pp. 157, with 7 illustrations. Philadelphia: J. B. Lippincott Company, 1913.

This is a handy little manual giving the principles of the taking of the blood-pressure, describing the instruments, of which the author naturally favors his own and points out the disadvantages of the aneroid instruments, and indicating the significance of the findings as showing pathologic conditions. The superiority of the auscultatory method of determining the reading of the diastolic pressure is emphasized. A brief account of the treatment of high and low blood-pressure is added. The book ought to be very useful to those who wish to inform themselves on the subject, a knowledge of which has become indispensable to the practicing physician.

Müller's Serodiagnostic Methods. Authorized Translation from the Third German Edition. By Ross C. Whitman, B.A., M.D., Professor of Pathology, University of Colorado School of Medicine. Cloth. Price, $1.50 net. Pp. 146, with 7 illustrations. Philadelphia: J. B. Lippincott Company, 1913.

Seriodiagnosis and immunity reactions have become so numerous and so complicated and are so extensively applied that the desirability of a reliable guide to the technic of the various procedures must be felt by laboratory workers as well as by students and practitioners in general. The present work is a translation from the third edition of the German original. The descriptions of the various methods are clear and the translation is excellent. One is surprised at the omission of Noguchi's modification of the Wassermann reaction, but we are informed in the translator's preface that this omission is at the request of its author. Some other methods have been added by the translator, but with these exceptions the translation follows closely the German original.

Medicolegal

Interdicted Information and Use of Decoy Letters

(Ackley vs. United States (U. S.), 200 Fed. R. 217)

The United States Circuit Court of Appeals, Eighth Circuit, affirms a conviction of the appellant Ackley of sending a letter through the mail furnishing information where and from whom articles could be obtained which would prevent conception. The articles he tried to sell were a "lady's syringe" and "sanitary powder." The court says that the statute is: "Every article or thing adapted . . . described in manner calculated to lead another to use it for preventing conception" is unlawful. The article may be of legitimate use; in fact it may not prevent conception, but if it is calculated to lead another to use it for such purpose it is unlawful. And that was what the appellant meant when he wrote his letter and when he sent it with the circular through the mail. It is the deposit for mailing that constitutes the offense and when that is done the offense is complete.

Complaint was made of the fact that the letters of the post office inspector to the appellant were answered under the assumed name of a woman, but for which the appellant's letters and pamphlet would not have been mailed. A party who persuades another to commit a crime is an accessory, and as a witness is to be considered as such, and his testimony weighed accordingly. But when officers, or even a private citizen desirous of enforcing the laws, believes from general information, and as in this case, from the pamphlet reciting "Woman's Doctor," "Woman's Friend," "Woman's Syringes," "Woman's Antiseptic Germ-Killing Powders," "Consultations only at my offices," "Syringes sent by freight only," then the officer had the legal, as he had the moral, right to send "decoy letters." It is now too late to complain of decoy letters in such a case.

Liability for Malpractice where Two Independent Physicians Are Employed

(Morey vs. Thybo (U. S.), 199 Fed. R. 760)

The United States Circuit Court of Appeals, Seventh Circuit, reverses a judgment for malpractice rendered against the defendant Morey for error in submitting to the jury a count in the declaration in which Mrs. Thybo alleged that he, "together with one Rice, another physician and surgeon whom the defendant then and there called in to assist him and for consultation," negligently tore and lacerated her vagina and uterus in delivering her of a child, failed to remove all of the afterbirth, and used unsterilized instruments, in consequence of which blood-poisoning developed.

The court says that the undisputed facts were that Morey alone was first employed; that he had no business relation, or even acquaintance, with Rice; that Mrs. Thybo and Rice were old-time friends; that Mr. Thybo, the husband, telephoned to Rice to come to the Thybo home; that after Rice's arrival at 10 p. m. he concluded from his examination that delivery was impossible without the use of instruments; that, by agreement of Rice and Morey, Rice was to use the instruments and Morey to administer the anesthetic; that this division of service was known to Mrs. Thybo and her husband, and not objected to; that deliveries of the child and of the placenta, Morey and Rice each doing his part, were effected during the early hours; that Morey left at 2 a. m., and Rice returned home at 4 a. m.; and that the subsequent treatment was by Morey.

Whether the forceps were sterilized or not was a matter of sharp dispute; but, of course, the jury's finding that they were not must be accepted. Rice brought his own instruments. After his examination and decision to use forceps, Morey went into the bedroom and got ready to administer the anesthetic. Mrs. Thybo was lying crosswise on the bed. Morey was at her head. After Morey was in that position, he did not see Rice until he came into the bedroom attired in surgeon's garb and with the instruments in his hands. There was no testimony that Morey saw the instruments before Rice brought them into the bedroom. Consequently no basis was afforded by the evidence for a finding that Morey knew of and acquiesced in the use of unsterilized forceps. By the exercise of reasonable diligence, under the circumstances, should he have known? Not unless, while attentively engaged in his own part of the service, he ought gratuitously to have entertained a suspicion that an apparently learned and skilful surgeon was about to commit a gross medical offense, and to have followed up the suspicion by inquiring whether his brother had forgotten to sterilize his hands and his instruments. No such unreasonable burden is imposed by the law.

When the afterbirth was delivered, Rice examined it, found it to be entire, and at once had it disposed of. Morey, from across the bed, looked at it, and to him it appeared to be intact. Nothing in the record warranted a finding that Morey knew that Rice had not removed all of the afterbirth. And here, too Morey was not bound to assume, in the absence of observable indications, that Rice was incompetent. Similarly, with respect to lacerations, Morey, from his position, could not know of them for himself; and from Rice's silence he was not negligent in inferring that no lacerations requiring repair operations had been inflicted. If Morey in his subsequent visits negligently failed to discover promptly and to treat properly the lacerations and the blood-poisoning, those were matters of his own direct responsibility.

Two physicians, independently engaged by the patient and serving together by mutual consent, necessarily have the right, in the absence of instructions to the contrary, to make such a division of service as in their honest judgment the circumstances may require. Each must not only bring to the case the ordinary knowledge and skill of the profession, but also give his best personal attention and care. Each, in serving with the other, is rightly held answerable for his own conduct, and as well for all the wrongful acts or omissions of the other which he observes and lets go on without objection, or which in the exercise of reasonable diligence under the circumstances he should have observed. Beyond this, his liability does not extend.

Communications Made in Presence of Third Parties

(Denaro vs. Prudential Insurance Company of America (N. Y.), 139 N. Y. Supp. 758)

The Second Appellate Division of the Supreme Court of New York says that it was contended that certain communications, to which physicians who had attended the plaintiff were permitted to testify over the objection that they were privileged, were made to the physicians in the presence of the insured's father or others near, and that, under the rule which prevails in reference to attorneys, where communications are made to them in the presence of third parties, it loses the character of a confidential communication, this testimony was not objectionable. The court does not think, however, that the situations are analogous. Where a client visits his attorney with an opposing party, and they all enter into a general discussion, or the attorney is asked to become a witness to the execution of a paper, etc., there is an obvious intent to make the communication public; but when a physician enters a house for the purpose of attending a patient, he is called on to make inquiries, not alone of the sick person, but of those who are about him and who are familiar with the facts, and communications necessary for the proper performance of the duties of a physician are not public because made in the presence of his immediate family or those who are present because of the illness of the person. Of course, the persons who are present are not denied the right to testify. It is only the physician who is bound by the rule; but it is absolute as to him, except in those exceptions provided by the statute. He is forbidden not to reveal communications from his patient, but "any information which he acquired in attending a patient, in a professional capacity, and which was necessary to enable him to act in that capacity;" and it is of no consequence how the information was acquired, whether by some one telling him, or by observation, or in any other manner.

Aggravation of Abnormal Mental or Nervous Condition

(Cook vs. Village of Mohawk (N. Y.), 100 N. E. R. 815)

The Court of Appeals of New York says that the plaintiff charged that the defendant had wrongfully obstructed a natural waterway in such a manner as to discharge the water on the plaintiff's lands, causing damage thereto and affecting the health of the plaintiff's wife, who was one of the occupants. Evidence was admitted which emphasized the element of emotional or mental suffering on the part of the wife when it should have been excluded. The defendant should not be held liable for the mental or nervous disturbance of the plaintiff's wife, due to a cause entirely separate from the flooding of the plaintiff's premises. The wife had a fibroid tumor. If this was responsible for a mental or nervous condition which made her unnecessarily apprehensive of the flooding of the land, and this increased her ailment, the defendant could not be charged with the consequences. Mental suffering is not a legal element of damages in such cases, and there can be no recovery, except for physical ills which can be ascribed directly and with reasonable certainty to the defendant's wrongful act.

Validity of Law Providing for District Hospitals for Treatment of Tuberculosis

(Brissel vs. State (O.), 100 N. E. R. 348)

The Supreme Court of Ohio holds that the act of the legislature of that state, approved March 23, 1909, which provides for establishing and maintaining of district hospitals for the care and treatment of persons suffering from tuberculosis, is a valid exercise of legislative power not repugnant to the constitution. The court says that it may be conceded that the law is not so full in some of its details as might be desired to give facility to its administration, but the court will not let its purpose fail of its beneficent result for this reason alone. In the absence of plain terms to require a different course, such a construction will be put on the statute as will prevent the failure of the manifest purpose of the legislature. The court will not by construction paralyze the arm of the joint board by denying to it the power necessarily incident to the actual and definite grant of authority.

When a board of commissioners has proceeded with the commissioners of other counties to the formation of a joint board referred to, and when that board has been formed and proceeded to the carrying out of the duties imposed on it by the statute, each of the counties whose commissioners have joined in the forming of the board has fixed and definite obligations, with reference to the hospital, which cannot be terminated at the mere will of any such county. The will of the majority must control, so long as it violates no provisions of the law.

Cousin Entitled as a Physician to Recover for Administering Anesthetic

(Epstein vs. Hugel (N. Y.), 138 N. Y. Supp. 1072)

The First Appellate term of the Supreme Court of New York reverses a judgment on a verdict for the defendant and orders a new trial, with costs to the plaintiff to abide the event, in this case where the plaintiff sued for his services, as a physician, rendered to the defendant. The court says that it was uncontradicted that the plaintiff visited the defendant in Connecticut and thereafter the defendant was operated on by a Dr. Goodman, the head of a hospital, and that the plaintiff assisted at the operation. But it was claimed by the defendant that the plaintiff, who was his cousin, when he called on him, first called only in a social way, and the defendant endeavored to meet the plaintiff's claim for compensation by claiming that there was a partnership between Dr. Goodman and the plaintiff, and that having paid Dr. Goodman $500 he should pay nothing whatever to the plaintiff for the services rendered by the plaintiff at the operation. The only evidence adduced by the defendant as to the existence of a partnership between the plaintiff and Dr. Goodman was evidence that the plaintiff and Dr. Goodman occupied the same house. The evidence was uncontradicted that the plaintiff assisted, with several other physicians, at the operation and that he personally administered the anesthetic to the defendant. The court thinks that he, at any rate, was entitled to recover for this service.

Evidence of Specializing as Touching Competency in Other Lines

(Klodek vs. May Creek Logging Co. (Wash.), 129 Pac. R. 99)

The Supreme Court of Washington affirms a judgment in the plaintiff's favor for damages for an alleged breach of contract on the defendant's part in the matter of furnishing him medical attendance when injured while in its employ. The defendant claimed to have been prejudiced by the introduction of a newspaper advertisement containing the name of the attending physician and describing his specialty and place of business: "Eye and Nose. 206-7 Marion Building." But the court is unwilling to hold that this was error. It says that it will take notice of modern tendencies and conditions in the medical profession, and if a physician holds himself a specialist along certain lines it is no discredit to him to show that fact, and from it raise the inference that he is not keeping up with practice in other lines. At any rate, he, or those relying on him, should not complain of the burden of meeting the *prima facie* showing. The basis of the charge in this case was that the physician was incompetent and unskilled. It was for the jury to say whether he was or not and the fact that he was specializing in other branches of the profession was a circumstance relevant to the issues.

Validity of State Quarantine Regulations

(Simpson vs. Shepard (U. S.), 33 Sup. Ct. R. 729)

The Supreme Court of the United States says that quarantine regulations are essential measures of protection which the states are free to adopt when they do not come into conflict with federal action. In view of the need of conforming such measures to local conditions, Congress, from the beginning, has been content to leave the matter for the most part, notwithstanding its vast importance, to the states and has repeatedly acquiesced in the enforcement of state laws. Such laws undoubtedly operate on interstate and foreign commerce. They could not be effective otherwise. They cannot, of course, be made the cover for discriminations and arbitrary enactments, having no reasonable relation to health, but the power of the state to take steps to prevent the introduction or spread of disease, although interstate and foreign commerce are involved (subject to the paramount authority of Congress if it decides to assume control) is beyond question.

Senile Dementia and Testamentary Capacity

(In re Purcell's Estate (Cal.), 128 Pac. R. 932)

The Supreme Court of California says that the will which this suit was brought to revoke was made by Mrs. Purcell when she was 71 years of age in anticipation of and shortly before a severe surgical operation on her. It was clear that, although the physician was of the opinion that, as a matter of medical science, her mind was not physically entirely sound, all he meant by that opinion was that she had a slight impairment of memory due to old age which led her to rely on others more than she otherwise would, but that she was nevertheless able to and always did think, talk and act rationally, and manage such of her affairs as she there had in hand with reasonable prudence and judgment. The witness himself appeared to believe that she should have decided about the operation without consulting her brother-in-law, who had been for years her trusted business manager. The medical profession may describe such a condition as senile dementia and declare such a person mentally unsound, but it does not constitute the sort of incompetency or insanity which, in the estimation of law and of men of ordinary sagacity and prudence, renders a person incapable of executing contracts or making a will. Her conduct and conversation, as detailed by physicians, rather tended to show that she herself was aware of her failing memory of recent events, and that she prudently chose to rely on others in whom she had confidence in her business affairs, and that in all other respects she had at least ordinary wisdom, judgment and mental capacity. If there were times when she was incapable of transacting business, the time when she executed the will was clearly one of her lucid intervals. A careful reading of the whole evidence brings the court to the conviction that on the whole case no reasonable person could believe that she had not sufficient mental capacity to make the will in question.

Admitting Lack of Experience or Skill

(Morrison vs. Altig (Ia.), 138 N. W. R. 510)

The Supreme Court of Iowa says incidentally, in this veterinary case, that even a practicing physician who informs a person employing him that he lacks experience or skill in the service he is asked to perform is charged with no liability on account of his professional incompetence. It cites Lorenz vs. Jackson, 88 Hun, 200; 34 N. Y. Supp. 652.

SEVENTEENTH INTERNATIONAL MEDICAL CONGRESS

August 6-12, 1913

(From Our Regular and Special London Correspondents)

(Concluded from page 893)

Section on Obstetrics and Gynecology

The Section opened August 7 under the presidency of Sir Francis H. Champneys with a discussion on "The Treatment of Hemorrhage from the Placental Site in the Late Months of Pregnancy." The essayists who introduced the discussion were Profesor Döderlein of Munich and Professor Essen-Möller of Lund. By arrangement the former confined his remarks to placenta praevia, and the latter to accidental hemorrhage. This accentuation of the natural tendency for the subject to fall into two divisions made the debate, it must be admitted, rather disjointed in character, but it became perfectly clear that the Section was unanimous in dividing all cases of hemorrhage into two groups for purposes of treatment: (1) Those for whom the facilities of a hospital or nursing home were available, and (2) those in which these were impossible. Practically every speaker urged this distinction and several, indeed, insisted that cases of hemorrhage were as clearly cases for treatment in nursing homes or hospitals as acute surgical conditions.

Professor Döderlein contributed an elaborate series of statistics of methods of treatment under the headings of (1) artificial dilatation by bags, (2) tamponade of the vagina, (3) Braxton Hicks' method, (4) intra-abdominal metreuryse, (5) abdominal cesarean section and (6) vaginal section. He favored operative measures, particularly vaginal cesarean section, for severe cases where facilities were possible, but was still prepared to keep an open mind on the subject, and all the more so since the more obstetrical methods gave a very low mortality. So far as the discussions related to placenta praevia, there appeared more or less a consensus of opinion that Braxton Hicks' method for most cases and cesarean section for severe cases with closed cervix gave the best prospects. Dr. Munro Kerr (Glasgow) urged that this latter should not be postponed till late. Dr. Murdoch Cameron was by no means enthusiastic for cesarean section, but Professor Recasens (Madrid) was sufficiently convinced of its merit to have done it in instances in which the child was dead. Professor Jardine (Glasgow) recommended pituitary extract for all cases of hemorrhage, but Professor De Lee (Chicago) pointed out that rupture of the uterus might follow this drug. Professor Davis (Philadelphia) regarded the condition as being essentially similar to ectopic gestation and therefore treated it on surgical lines. Prof. Paul Bar (Paris) and others called attention of the possibility of an aggravation of shock following section cases, but did not exclude it as a form of treatment. Professor Essen-Möller, limiting himself to the pathology and treatment of accidental hemorrhage, expressed his conviction that a small group of cases are directly attributable to trauma, but that the majority of cases have an association with albuminuria such as to suggest some general intoxication—some condition analogous to eclampsia. For treatment he advocated cesarean section (abdominal or vaginal) for serious cases with closed cervix when the condition made rapid delivery necessary; hysterectomy was only to be done when contraction remained obviously deficient after removal of the child or placenta. He doubted the efficiency of the Rotunda method and in cases of moderate severity would try the effect of rupture of the membranes. Discussing accidental hemorrhage Sir John Byers (Belfast) recommended the Rotunda method of packing, pituitary extract and isotonic salines. Professor Jardine (Glasgow) described two cases of concealed hemorrhage in which the condition was too serious for section and yet the patient recovered under pituitary extract, salines and morphin. Such cases pointed a moral. Dr. Hastings Tweedy (Dublin) described thorough plugging of the vagina and its fornices as being invariably successful in arresting bleeding; the patient, however, might still be in danger.

At the afternoon session (August 7) Professor Frank (Cologne) spoke enthusiastically in favor of subcutaneous symphysiotomy based on an experience of 117 cases. He did not consider infection to be a contra-indication. Professor Favre (Lyons) described an ingenious method of external hysterography. By means of a very simple apparatus which he showed, he had studied the uterine contraction during pregnancy, labor and post partum. Different types of contraction have been noted and it has been found possible to foretell the type of contraction in labor. The action of various drugs had also been studied with care. The communication was listened to with much interest.

At a joint meeting of Sections on Obstetrics, Pediatrics and Hygiene on Friday, August 8, Dr. Chalmers (Glasgow), Dr. Koplik (New York) and Professor Wallich (Paris) reported on the causes of death among infants during the first four weeks after birth. The first of these expressed the opinion that two-thirds of this mortality was to be ascribed to causes suggesting cell-deterioration in the antenatal state. This influence showed no dependence on surroundings and knew no geographical boundaries, but further tabulation of the causes of death in the days and weeks of the first month were urgently necessary for our further information.

Dr. Koplik expressed a somewhat similar opinion as to the importance of prenatal influences. The small quota of syphilis was probably due to the difficulties of diagnosis at so early an age. He considered that 60 per cent. of this deplorable mortality was due to a combination of these prenatal influences with ignorance, neglect and poverty.

Professor Wallich produced interesting statistics showing the variation between legitimate and illegitimate births and between home-nursed infants and those put out to nurse. The mortality from obstetric reasons was decreasing, but much remained to be done in correcting detrimental social conditions.

Many of the succeeding speakers emphasized the incidence of syphilis, more especially Miss A. Louise McIlroy (Glasgow), who startled the meeting by announcing that 49 per cent. of 100 unselected women from an outpatient clinic showed a positive Wassermann reaction. All the families of nine negative mothers also proved positive. This was regarded as indicating an unsuspected degree of latent syphilis.

Sir Francis Champneys decreed that it must be again made fashionable for women to nurse their own children; schools for prospective mothers would in the end prove a cheap investment for the state.

Other speakers were anxious that the statistics should be amplified by the compulsory notification of all cases of stillbirths, while some went so far as to recommend that pregnancy should be made a notifiable disease! Only thus, they said, would efficient supervision of the pregnant woman be obtained.

Dr. T. W. Eden hoped that wet-nursing would be reintroduced on a large scale; there was sufficient healthy human milk for all infants in the world and the whole difficulty was one of distribution.

In the afternoon session of the Section on Obstetrics Professor Pozzi (Paris) described his operation for opening up stenosed cervices associated with sterility, and was enthusiastically supported by Dr. H. Spencer, who regretted that this operation was not better known in England and America. Professor Beuttner (Geneva) recommended an original operation for chronic inflammatory disease of the appendages where it was possible to preserve one ovary, whereby a wedge of the uterine fundus was removed in one piece with the adnexa; the possibility of menstruation was thus left to the patient.

Miss A. Louise McIlroy (Glasgow) discussed some factors influencing the mammary secretion and was constrained to limit such to the ovary. She had failed to confirm Shäfer's experimental work on the galactogogue action of the pituitary gland.

Discussion on Roentgen and Radium Therapy

The Obstetrical and Radiological Sections met August 11, to discuss in joint session the subject of "Roentgen and Radium Therapy in Gynecology." Dr. Albert Schönberg (Hamburg) communicated his results in a paper amplified by carefully tabulated statistics. His report included forty-six cases of myomas, twenty-six of carcinomas, thirty-five of fibrosis uteri, a short series of menstrual abnormalities and some cases of pruritus vulvae; all of these were treated by x-rays. Experiments have proved that the rays have a definite deleterious influence on the male and female genital glands. Their influence on myomata, however, is not solely due to ovarian atrophy, but includes a direct action on the myomatous stroma. The great percentage of myomata did not disappear under treatment, but the percentage of complete relief from symptoms was high. Lasting cure was to be expected with certitude in favorable cases, but a certain number of myomata proved quite refractory; he did not consider that the indications for favorable cases were yet definite. He summed up the general indications for x-rays in gynecology as follows: 1. Induction of menopause. 2. Removal of post climacteric bleedings. 3. Soothing menstrual difficulties at all ages, if possible without sterilization. He preferred to use as few rays as possible and to regulate by a varying exposure. Hemorrhage might increase after the first or second dose, but later decrease.

Dr. Foveau de Courmelles (Paris) made it clear in his opening sentences that neither radium nor x-rays must be regarded as a panacea for all gynecologic ills. He had, however, treated fibroids for the past ten years with x-rays, and, when applied discriminately, was convinced of their great utility. His technic included aluminum filtration (1 mm. in thickness). Hemorrhages and pains or feelings of weight were usually the first to go, but young fibromas, even when of a large size, yielded rapidly. The action was much more rapid about the menopause, but failure occasionally occurred even after a preliminary improvement. Contra-indications were (1) polypi and (2) degenerating tumors. Discussing radium, Dr. Foveau de Courmelles gave a very favorable report in malignant diseases: Of 100 cases of inoperable carcinoma 70 per cent. had improved for from one to four years. The mobility of the uterus increased, hemorrhages and leukorrhea diminished and general improvement rapidly appeared. He applied 1 to 5 cgm. of pure radium to the neck of the uterus for from six to twenty-four hours. He hoped that bad as well as good results would be published.

Professor Kroemer narrated the excellent results obtainable with mesothorium in the treatment of malignant diseases. Professor Döderlein enthusiastically supported the claims of radium and mesothorium and showed lantern slides in natural color of cases in process of treatment. His emphatic stand greatly impressed his hearers. Dr. Jacobs (Brussels) preferred radium to radical operation in extensively malignant cases. He used massive doses and had had cures for from three to three and one-half years. Dr. Walter Tate had not yet seen postoperative recurrences disappear under the treatment. Professor Nagel (Berlin) gave his patients every opportunity of x-ray treatment by experts, but was not greatly impressed by the results. He gave the advice to the Section to "wait and see."

The discussion as a whole was very favorable to nonoperative treatment, but Dr. Spencer emphasized some of the dangers. He considered that every case treated should be at the same time under the care of a gynecologist, and pointed out the possibilities of degeneration or malignancy and the disadvantage of sterilization.

Space will allow only brief comment on the more important topics in the other sections.

The Nature of Cancer

At a combined meeting of the Sections of Chemical Pathology and Bacteriology, held on "The Nature of Cancer," Dr E. F. Bashford, Director of the Imperial Cancer Research Fund, opened the discussion. As the result of the work done by himself and his co-workers for several years on the lower animals, supplemented by observations of the conditions under which cancer occurs in all parts of the world in man, he concluded that it was unlikely that a parasite played any part in the causation. All we know for certain is that some form of irritation is traceable in practically every form. Dr Freund of Vienna was the next speaker. He had been able to demonstrate substances in normal cells which are antagonistic to cancer, and substances in cancer cells which stimulate them to further work. The former substances prevent cancer but the latter destroy the former. Dr. Clowes of Buffalo thought that the equilibrium of the cancer cell depends on the equilibrium of its membrane, which in its turn depends on the equilibrium of the lipoid content of the cells, or, in other words, on its electrolytic content.

The Prevention of Typhoid Fever

In the Section of Naval and Military Medicine a discussion on "Prevention of Typhoid Fever" was opened by Professor Vincent of the Val-de-Grace Hospital, France. After prolonged consideration and experiment the French military authorities decided to introduce inoculation against typhoid fever as a voluntary measure at the beginning of 1912. It is now obligatory in the African colonies. Unpleasant effects rarely occurred and were, as a rule, due to the patient being in an unsuitable condition, ill, tired or recovering from a disease. The vaccine used was polyvalent, being the result of the cultivation of ten different strains of the bacillus; it contained 400 millions of bacilli per c.c. The results have been most satisfactory. In Eastern Morocco not one man of 992 vaccinated contracted typhoid fever, whereas among those not vaccinated 4 per cent. were attacked, and of these one in seven died. Col. Sir William Leishman followed with a description of the work done in the British Army, especially in India. Contrary to the French method, the vaccine was made from only one strain of the bacillus, but the results were no less satisfactory. In the ensuing discussion attention was drawn by several speakers to the great value of vaccine treatment in the course of the disease.

"Hormones" and "Chalones"

In the Section of Physiology the most important paper was that on the internal secretion by Prof. Schäfer. He pointed out that convenient term "hormone" introduced by Starling (from ὁρμάω, I excite) while applicable to the active principle of many internal secretions, had been extended to all and was wrongly applied to principles which did not excite, but checked activity. For these he suggested the term "chalone" (from χαλάω, I relax). It was, however, desirable to have a term which included both the hormones and chalones. The one quality which distinguished them was their drug-like effect on the organs and tissues. A convenient term, suggested by Prof. W. R. Wardie, was autacoid substance.

Radium in Dermatology

In the Section of Dermatology, Mr. Hayward Pinch, director of the Radium Institute, London, opened a discussion on the use of radium in skin diseases. He held that radium was the best treatment for many diseases, such as rodent ulcer, warts and painful corns. Certain forms of eczema of a chronic localized type yielded to one application of the half-strength applicators, while psoriasis—though as with every treatment recurrent—disappeared for some time after a dose of only five minutes' duration. Moles and deep-seated vascular nevi—dangerous to attack with the knife—vanished completely if patiently treated. For keloid radium was the only treatment of value. The leaders of the French school of radium therapy, Wickham, Degrais and Bellot, followed and amply confirmed the English experience.

Treatment of Syphilis

Perhaps the meeting of the Congress which attracted the most attention was a joint session of the sections of Dermatology and Syphilography and of Naval and Military Medicine on the treatment of syphilis by salvarsan and allied substances. The discussion was opened by Professor Ehrlich. He agreed with those authorities who maintained that the action of salvarsan is not direct, but requires a third factor for its completion, which must be sought for in the tissue fluids of the body. Salvarsan could be anchored by the spirochetes in the test-tube but they were not killed. This could be completed only in the living body. He next discussed the toxicity of salvarsan. He had found that rabbits were killed by 0.1 to 0.12 gm. of the alkaline solution, while the acid solution was still more poisonous. He then passed to the febrile reactions observed in its therapeutic use. Some of these were due to technical errors of administration or to administration in the roseolar stage, when the body is saturated with spirochetes. The febrile reaction was due to destruction of the spirochetes and setting free of their toxins. It could be prevented by previous preliminary treatment with mercury. As to the recurrences, about which so much had been written, his opinion was that they were due to insufficient treatment and that a good many deaths were due to the same cause. The mortality after two or three million injections compared very favorably with that of chloroform anesthesia. There were frequent deaths from mercurial treatment, many of which were not recorded. It is curious that Professor Ehrlich did not allude to the fact, attested from many quarters, that deaths from salvarsan have also been suppressed. Deaths with cerebrospinal symptoms were due to want of care in selection of the cases. Here again he did not face the fact that in one well-known type of fatal case coma and convulsions occur, and it has repeatedly been recorded that the patients were young and robust and apparently ideal subjects for salvarsan Nor did he refer to the fact that this result and others, such as jaundice, nephritis and eruptions, can only be explained as manifestations of arsenical poisoning. Deaths could be avoided, he said, by giving very small initial doses. In the discussion which followed Lieut.-Colonel Gibbard said that he had obtained the best results from a course of two injections of 0.6 gm. salvarsan and nine intramuscular injections of mercury prolonged over nine or ten weeks. In over 3,000 injections of salvarsan there had not been a single death. Professor Wassermann said that the experiences at his laboratory had shown that before the introduction of salvarsan it was rare for a positive reaction of the blood to be converted into a negative one. In cases of fresh infection it was easy by salvarsan to convert a positive into a negative reaction. But if the infection had existed for three or four years it was difficult to remove the positive reaction. This he thought was due to adaptation of the spirochete to its environment. Hence the importance of attempting to sterilize the patient in the early stage. If symptoms of infection of the central nervous system were present it was doubtful whether sterilization could ever be accomplished. Professor Hata, the collaborator of Ehrlich in the discovery of salvarsan, stated the results which had been obtained under his direction in the hospitals of Japan. In 166 cases thirteen relapses had occurred within periods varying from six months to a year. Professor Blaschko of Berlin advised caution in speaking of cures. An interval of ten years must elapse before this could be done. Dr. Fordyce of New York had given between 6,000 and 7,000 injections with only one death. He found that in early cases six injections of salvarsan with ten or twelve of mercury were sufficient. In secondary cases he gave several such courses. Dr. Levy-Bing of Paris said that in twelve cases of early syphilis injected from the third to the thirteenth day after the appearance of the chancre seven had relapsed within a year. In replying Professor Ehrlich said that there were dangers from the administration of too much salvarsan on the one hand and too little on the other. If the drug had not been proved to fulfil the results which he had at first hoped for, at any rate it was a valuable adjunct in the treatment of syphilis.

State Control of Syphilis

At a joint session of the Section of Dermatology and Syphilography with the Section of Forensic Medicine a discussion took place on "Syphilis: Its Dangers to the Community and the Question of State Control," opened by Professor Blaschko (Berlin) who related how the German Society for the Prevention of Venereal Diseases was founded in 1902. This society was consulted by the government, and many laws were passed at its instigation. The regulation of prostitutes had never been of the slightest use in diminishing disease, for it missed the most important class—the young clandestines. Police supervision of any kind was unsatisfactory. A board of health should be constituted and a system of registration of disease applied to both sexes. Professors Gaucher and Gouterot of Paris also condemned the state regulation of prostitutes. They recommended education of the young, organized treatment of syphilitic prostitutes, suppression and prevention of prostitution by the recognition of paternity, and the conferring on seduced virgins the rights of wives. Dr. Woods Hutchinson (New York) recommended notification which in the form of an anonymous communication by the physician was rendering excellent service in New York. The following resolution was adopted unanimously:

> That, sensible of the ravages wrought by syphilis in the community and deploring the inadequacy of existing facilities for the checking of its dissemination, the International Medical Congress calls on the governments of all the countries here represented (1) to institute a system of confidential notification of the disease to a sanitary authority where such notification does not already obtain, and (2) to make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for.

This resolution was also adopted by the whole congress at the closing general meeting.

The Increase of Lunacy

Sir James Crichton-Browne, the President of the Section of Psychiatry, gave an address in which he stated that all countries from which trustworthy statistics were available showed an increase in the number of lunatics out of proportion to the increase of the population. Comparing the United Kingdom of to-day with it in 1859, the notified insane had increased by 276 per cent. while the population had increased only by 87 per cent. This disquieting fact cannot be fully accounted for by more accurate registration, or by accumulation in asylums of chronic patients. There seemed to be no good reason why insanity should have increased while the health and material condition of the people had markedly improved. The segregation in asylums of a growing number of the insane during the period of sexual activity ought to have diminished hereditary insanity. There were also other factors which should have checked insanity—the diminished consumption of alcohol, the better treatment of tuberculosis and the diminution of puerperal sepsis and syphilis.

The Prevention of Beri-Beri

In the Section of Tropical Medicine a discussion was held on beri-beri in which most of the present-day investigators of the etiology of the disease took part. Professor Eijkmann of Utrecht pointed out that from the standpoint of the deficiency theory it should be remembered that the need of the body for vitamine varied somewhat in the individual, sex, mode of life, occupation, residence, climate and season. The following resolutions were carried by a large majority:

> 1. In the opinion of this section beri-beri among natives, whose staple food is rice, is induced by the continued and too exclusive consumption of the grain in its highly milled form, by which treatment the cortical and subcortical layers are removed.
>
> 2. The section urges on all authorities responsible for the health of native communities the encouragement, by every means in their power, of the restriction of the use of rice of this kind.
>
> 3. In view of the proved non-infectiousness of beri-beri, the section suggests to all port authorities the propriety of abolishing quarantine and the restrictive measures at present in operation.

These resolutions were also adopted by the whole congress at the closing meeting.

The Museum of the Congress

The Museum of the Congress contained 4,000 different exhibits illustrating for the most part various aspects of recent medical progress, arranged according to the various sections. For the first time there was a department devoted to museum technic. This departure was due to the initiative of the International Association of Medical Museums and was carried out by Dr. Maude E. Abbott. Beautiful specimens were exhibited by Professor Spalteholz of Leipsic showing his method of rendering tissues transparent. Professor Houser of Erlangen showed a series of sections through the whole of the body in different directions.

Professor Wahby of Cairo exhibited the results of injecting various vessels with fusible metal to show their branches. Dr. R. H. Clarke showed a remarkable apparatus by which any particular part in the brain may be localized and reached without damage to adjacent parts. It consisted of a framework placed horizontally on the head, above which was a corresponding frame. On the upper frame was a traveling crosspiece arranged to move either backward and forward or from side to side. It carried a needle, by raising or lowering of which the point could be brought to any part of the brain. Specimens had been brought from all over Europe to illustrate the development of the ovum. A remarkable and apparently so far unique specimen was shown by Dr. F. J. M. McCann of London. It was an ovarian pregnancy in which a four-month fetus was situated in one of the cavities of a multilocular ovarian cyst. The exhibit of Dr. Edwin F. Smith of the United States Department of Agriculture, showing a disease of plants produced by inoculation with a microbe which he claimed to be analogous to cancer in animals, attracted much attention.

4 *Nucleus Cardiacus Nervi Vagi and Three Distinct Types of Nerve Cells Which Innervate the Three Different Types of Muscle. E. F. Malone, Cincinnati.

4. **Nucleus Cardiacus Nervi Vagi.**—Malone says that the histologic character of a nerve cell is an indication of its function. Differences in connections with portions of the organism which differ merely in spatial relations do not involve a difference in the character of the nerve cells, but are associated merely with the location of the nerve cell; for instance, arm and leg muscles, flexors and extensors are all innervated by the same type of cell, although such differences in peripheral connections correspond to differences in the position of the corresponding nerve cells. The three types of muscle are innervated by three distinct types of nerve cell, which, however, are related to one another in such a manner that the cell innervating heart muscle is of a type intermediate between the other two types of cells. The nucleus cardiacus nervi vagi is situated in the middle portion of the sympathetic nucleus of the vagus.

13 Famous Case of Mary Toft, Pretended Rabbit Breeder of Godalming. C. G. Cumston, Boston.

5. **Treatment of Puerperal Eclampsia.**—Since the cause of eclampsia is still unknown, Peterson emphasizes that its treatment must of necessity be empirical. In a large series of cases of eclampsia prompt delivery gave a maternal mortality of 15.9 per cent., as compared with a maternal mortality of 28.9 per cent. where the delivery was long delayed. Where the uterus is emptied immediately or very soon after the onset of the first convulsion, the maternal mortality is still lower. While in a large group of cases the maternal mortality is 5 per cent. in favor of conservative treatment and spontaneous labor in cases occurring before 1900, between 1900 and 1912, on account of better and more prompt obstetric surgery, the figures are reversed and show that the maternal mortality is lower by 4 per cent. after the radical opposed to the conservative treatment of the complication. Therefore, the treatment of antepartum eclampsia should consist of emptying the uterus as quickly as possible after the onset of the first convulsion. The operative procedure which will empty the uterus the quickest with minimum trauma and shock to the eclamptic mother and child should be selected.

6. **Elastic Area in Isthmus of Uterus.**—The change which Ladinski has invariably found in early uterine pregnancy (first published six years ago) consists of a circular area situated in the median line of the anterior surface of the body of the uterus, just above the junction of body and cervix, that is to say, at the isthmus of the uterus, which varies in size according to the duration of pregnancy, and offers to the palpating finger the distinct sensation of elastic fluctuation. It can frequently be made out as early as the fifth week, when the area is only the size of a fingertip; but it can always be felt in the sixth week, when it is somewhat larger. As pregnancy advances this area increases in size in a crescentic manner, and extends upward toward the fundus until the third month of pregnancy, when nearly the entire anterior body of the uterus presents a fluctuating, cystic feel to the examining finger. The change in the consistency is observed in the anterior wall when the pregnant uterus is in the normal position or slightly retroverted; in extremely retroverted or retroflexed uteri the elastic area is found in the posterior wall, but the sign is usually felt a week or so later than in uteri of normal position.

Bimanual palpation is a prerequisite in eliciting this sign; while the uterus is fixed by counterpressure with the external hand, the anterior wall of the uterus, from the tip of the cervix to the fundus, is palpated with the internal finger or fingers, and if pregnancy exists, the elastic fluctuating area will be felt in the median line of the body of the uterus, immediately above the cervix. Ladinski says that there is no special skill or dexterity required to recognize this elastic area; the ordinary technic and tactile sense necessary in the performance of bimanual palpation will readily detect the difference in the consistency of the isthmus, and a proper interpretation of the character of this change will invariably establish a correct diagnosis. This can be done by the general practitioner as readily as by the specialist; a fact that enhances the importance and value of the sign.

As the result of a careful study of extensive clinical material, Ladinski concludes that this sign is not only constant and reliable and can be detected with greater ease than any other objective sign, but that it is undoubtedly the earliest sign of pregnancy. He insists that any change from the normal in the consistency of the isthmus of the uterus may be regarded with suspicion of pregnancy. The only conditions that show a change in the consistency of the isthmus, are pregnancy, subinvolution, that is, the result of pregnancy, and cystic tumors in the anterior wall of the uterus. In subinvolution, following delivery at term or abortion, there is a change in the same area, but the feel is very soft and doughy, in contradistinction to the tense, elastic and cystic feel of pregnancy. However, in the presence of a soft myoma, or cystic fibroid in the anterior wall of the uterus, the elastic feel elicited in the uterine wall is almost identical with that of pregnancy; and this is the only condition which cannot be differentiated from early pregnancy at the first examination. This is especially true when a soft myoma of the uterus is associated with amenorrhea, as is frequently the case. Under these circumstances further observation and repeated examinations will be necessary to establish a diagnosis.

20. **Ventricular Systole.**—The following summary is made by Swan and Janvrin of their work: The normal V_s-S time is from .085 to .10 second. It varies widely in certain abnormal conditions of the heart and circulation. The presphygmic period, as determined by calculation from simultaneous tracings of the apex beat, subclavian and radial pulses, is about .015 second shorter than the V_s-S time, and runs parallel to it, variations in one fairly accurately representing vairations in the other. They doubt the accuracy of the presphygmic period as obtained by this method and hope to settle this point more definitely in future work. In cases of auricular fibrillation the variations in the V_s-S time depend on: (a) the length of the preceding diastole, and (b) the strength of the preceding systole or systoles; being longest after a short diastole, and a strong systole, and *vice versa.* After diastoles of a certain length, however, the length of the V_s-S time varies little or not at all. From figures obtained in three cases, the length of diastole necessary for complete rest apparently lay between .322 and .330 second. In cases of broken compensation, the mean V_s-S time was invariably lengthened, except when a marked degree of arteriosclerosis was present. It is probable that, when no disturbing factors coexist, the length of the V_s-S time may be of value in estimating the capability of the heart muscle.

In every one of five cases on which tracings were taken with the patients lying and standing, the V_s-S time was definitely longer in the erect posture. As by far the greatest lengthening occurred in the two cases which were clinically regarded as having the least competent hearts, it is probable that the degree of lengthening may prove to be of value in prognosis. Aortic regurgitation shortens, and mitral valve lesions lengthen, the V_s-S time. Combined lesions, having opposite effects, tend to offset one another. A marked degree of arteriosclerosis shortens the V_s-S time. The relation of the V_s-S time to blood-pressure is not constant. It tends, however, to become shortened when the pulse pressure is high, especially if at the same time the diastolic pressure is low. The opposite also holds good. Split "C" waves in the jugular tracings were not associated with abnormally long V_s-S times. The speed of the pulse wave in the arm varies with extremes of blood-pressures, being faster in cases with high, and slower in cases with low, blood-pressure. This relationship, however, is not constant. No other factors seem to have any definite effect on the pulse speed. Although it varies widely in different individuals, it is nearly always constant in a given vessel of the same individual.

21. **Relation of Hypophysis to Growth.**—Summarizing the entire field of the rôle of the hypophysis in the growth of the individual in acromegaly in which there exists abnormal development of certain portions of the body, especially in their bony structures, Lewis and Miller state there is apparently hypersecretion of the anterior lobe. In the Fröhlich syndrome of adiposity and failure of sexual development, it is thought by many that there is lessened function of the posterior lobe; experimental information, however, suggests lessened secretion of the anterior lobe, but evidence on this point is not especially convincing. Regarding studies in metabolism in patients with acromegaly, there is again nothing conclusive, and more work must be carried out on this subject before it can be accepted that lessened katabolism takes place as compared with the normal individual.

Turning to the results of partial removal of the hypophysis in animals, only one point having a direct bearing on this subject seems to have been determined, viz., that partial removal of the anterior lobe, when performed on young animals, modifies growth and sexual development in such a manner as to resemble very closely the Fröhlich syndrome. Removal of the posterior lobe, apparently, has no effect on growth. This is a distinct contradiction to those who believe lessened function of the posterior lobe is responsible for the Fröhlich syndrome. Feeding experiments, on animals, fail to furnish any definite evidence that the administration of either the anterior or posterior lobe has any effect on growth.

23. **Effect of Diuretic Drugs on Life of Animals with Severe Acute Nephritis.**—The following conclusions are made by Walker and Dawson from their work and it is held that they suggest a similar effect in man. The diuretic drugs, theocin, caffein and potassium acetate definitely shorten the life of a rabbit having a severe acute experimental nephritis produced by uranium nitrate. Theocin and potassium acetate gave quite parallel results and were slightly more harmful than caffein. Spartein sulphate, although not nearly so detrimental as the other drugs, however, did, in some cases, shorten the animal's life. Water in large amounts is detrimental in some cases, possibly depending on the severity of the nephritis. The diuretics alone in large doses and water alone in large doses when given intravenously to normal animals for a reasonable length of time do not shorten their life and probably are not toxic in themselves. Diuretics are probably contraindicated in severe acute nephritis in man, since in animals in such cases they shorten life.

27. **Functions of Diaphragm.**—Movements of the costal borders during respiration, Hoover found, give valuable aid in differentiating between supraphrenic and subphrenic disease. Also in differentiating between pulmonary consolidation and pleurisy with effusion, and in differentiating between obsolete pleurisy and pleuritic effusion.

Costal border movements enable us to form a comparative estimate of a degree of pulmonary emphysema which exceeds mere filling of the pleural sinus with aerated lung. Movements of the costal borders give indication of the amount of fluid in a pericardial sac and also contribute to an appreciation of cardiac enlargement and an appreciation of the relative enlargements of the two ventricles. Unlike the diaphragm phenomenon of the pleural sinus, these movements of the costal borders and the subcostal angle are always present and can be accurately observed whatever the disease may be and however thick may be the panniculus adiposus. So these signs have a much broader and more accurate diagnostic significance than the so-called Litten diaphragm phenomenon. In making an estimate as to whether a costal border is stationary or diverges from, or is drawn toward the median line, the examiner should apply his thumbs symmetrically placed along the costal borders to serve as indicators. Inspection alone without the aid of palpation of the borders may lead to confusion between elevation of the thoracic cage and widening of the subcostal angle. The thoracic cage may be strongly elevated and still the subcostal angle remain the same size. In fat persons, asymmetrical movements of the costal borders may be obscured without the aid of indicatory palpation.

28. **Variations in Thyroid Colloid.**—The iodin content of the thyroid glands of rabbits serving as test animals was found by Jones and Tatum to be increased directly by feeding commercial desiccated thyroids, and indirectly, by intravenous injections of serum from hyperthyroid rabbits. The iodin content of the thyroid gland was found to be decreased by intravenous injections of serum of thyroidectomized rabbits. Following normal serum injections, the iodin content was sometimes increased, sometimes decreased, or remained constant, indicating individual variations in thyroid activity.

29. **Source of Urinary Indol-Acetic Acid in Dementia Praecox.**—The urinary indolacetic acid in the case of two patients studied by Ross was endogenous.

30. **Cultural Results in Hodgkin's Disease.**—In three cases of Hodgkin's disease Bunting and Gates secured a pure culture of a pleomorphic diphtheroid organism. In two other cultural attempts the organism was recognized, but was not secured in pure culture, and in a sixth case a similar organism, morphologically, was stained in the lesions of a primary intestinal Hodgkin's case. The detailed biologic reactions of this diphtheroid organism have as yet not been completely worked out by them. The strain recovered from the second case, however, has been found to grow readily at 37 C. on the media used to secure the cultures and on ordinary agar-agar. On glycerin-phosphate-agar the growth is almost as luxuriant under strict anaerobic as under aerobic conditions. For luxuriant growth, marked moisture of the medium seems necessary. On a relatively dry medium, growth is slow, and the organisms are found to develop as the long forms, granular, banded, and with many club-shaped involution forms. Branching forms are also noted. These forms are especially well developed on the egg-medium, where they also seem to have a tendency to cohere, so that in stained smears one gets many small groups of organisms radially arranged, with clubbed peripheral elements, somewhat suggestive of a minute actinomyces colony, as seen in section. On moist serum tubes with luxuriant growth, the organisms are short and plump, with polar staining. Many of these forms are coccoid. The authors have noted also, as emphasized by Negri and Mieremet, that in all old cultures coccoid forms predominate, and also that large spherical involution forms are present. A colony or a streak, which at twenty-four hours shows entirely the bacillary form, will twenty-four or forty-eight hours later show an apparent outnumbering of the bacilli by the coccoid elements. The organism stains by the Gram method, though the short plump forms hold the dye less strongly than the longer bacillary forms. It is not acid fast. No spore formation has been noted. The growth of the organism is at first glistening and grayish, but becomes more opaque and of a white color. Apparently, depending somewhat on the reaction of the media, there may be in some early cultures a slight greenish-yellow tint produced. Old cultures on glycerin-phosphate-agar become brownish, and the media itself darkens. Gelatin is not liquefied. There is no early change in reaction in litmus milk. Bouillon is not clouded by the growth. Flecks appear along the side

of the tube, and a slimy deposit gradually accumulates at the bottom. Plate cultures show a rounded colony with quite regular edge, a fine stippling of the growth and a central dark spot. The colonies are of a glistening gray color at the end of twenty-four hours, becoming gradually of an opaque white color. Altogether, these studies thus far seem to indicate that the authors were dealing with the same organism described by Negri and Mieremet.

38. **Compound Fracture of Base of Skull.**—Burnham has analyzed thirty-five cases of compound fracture of the base of the skull admitted to the Presbyterian Hospital, New York City, between June 1, 1908, and January 1, 1913. These cases all presented the classical picture of fracture of the base of the skull to which was added bleeding from the nose, mouth or ear. Cases which were surely basal fractures, but in which there was some doubt as to the diagnosis of compound fracture, were not included in this report.

Of these thirty-five patients fourteen died and twenty-one recovered, a general mortality of about 40 per cent. Six patients died during the first forty-eight hours, all in primary shock from the injury received. Eight patients died after the third, and before the fifteenth day, after having partially or wholly recovered from the shock of the injury: Of the eight patients, five died of meningitis. The causes of death and the day on which it occurred in the fatal cases are as follows: Five patients died of meningitis on the fourth (2), sixth (2), and thirteenth day, respectively. Two patients died of broncho-pneumonia on the fourth day. One patient died on the tenth day after secondary hemorrhage and operation.

From these figures it may be seen that, even in those patients who survive the primary shock following compound fracture of the base, there is still a high mortality—in this series 25.5 per cent.

39. **Experiment in Teaching Pharmacology.**—Crawford has become convinced that pharmacology should, like physiology, be taught as a pure science, as much in connection with the university as with the medical school, while the practical applications of pharmacology should be in the hands of scientifically trained clinicians who are specializing in therapeutics and who would be in closer touch with the medical work. Insofar as this point of view is concerned, the necessity for any separation of the department of pharmacology from the university seems unfortunate, as it would tend to lay too much emphasis on the attainment of immediate practical results, and by this separation many pure scientific workers would be lost to pharmacology. For economic reasons it is usually more expedient to have the department of pharmacology in connection with the medical school, but under ideal conditions all of the medical school should be in close relation with the rest of the university. The tendency of teaching in pharmacology is to overload the student with facts, whereas the main purpose should be to teach him to think logically and judicially in this field. It seems to Crawford that emphasis should be laid on the laboratory teaching pharmacology. Pharmacology has now become such a large field of knowledge that it hardly seems fair to expect one man to teach it along with another branch, such as clinical therapeutics, because the experience required to successfully teach clinical therapeutics is of a different kind from that required to teach pharmacology, and one is very apt to neglect one subject for the other. Many schools now recognize that there are two sides to modern therapeutics and to meet this are offering courses in experimental therapeutics. Such courses must be really an extension of the work in pharmacology, pathology and bacteriology. Successful teaching in pharmacology depends on the man, not on the rules.

52. **Colorimetric Determination of Epinephrin.**—Attention is called by Seidell to the defects of the previously proposed potassium iodate method for commercial suprarenal glands and explanations of the sources of error in it are given. The phosphotungstic acid method of Folin and Denis has been applied to a series of desiccated suprarenals and, although it possesses many excellent features, certain disadvantages which apparently render it unsuitable for the standardization of commercial glands, are pointed out. The gold chlorid reagent was

found to yield a maximum color only when a definite ratio was maintained between the amount of epinephrin and of gold, thus seriously restricting the practical quantitative application of this reagent. The new method proposed in the present paper consists in the use of manganese dioxid as the reagent for developing a color with aqueous epinephrin solutions or suprarenal gland extracts. The color so developed is estimated by comparison with artificial color standards made by mixing cobalt chlorid, gold chlorid and water.

53. **Depressor Substance of Urine and Tissues.**—The author's attempts to isolate by the methods of Kutscher, Lohmann and Engeland the depressor substance occurring in the urine, pancreas and duodenal loops of the dog, and which have an effect on blood-pressure analogous to that of B-iminazolylethylamin, failed.

56. **Action of Rennin on Casein.**—The conclusions drawn by Bosworth from his investigation are as follows: A solution of calcium caseinate neutral to litmus and free from all other salts is not curdled by rennin. A solution of calcium caseinate acid to litmus, which contains two equivalents of base for each molecule of casein, is curdled by rennin. Solutions of ammonium, sodium or potassium caseinates are not curdled by rennin. In such solution, however, the casein is changed to paracasein, the paracaseinates of these bases being soluble. When paracasein is produced from casein by the action of rennin no other substance is formed. Two molecules of paracasein are produced from each molecule of casein as a result of this action. Rennin is not, strictly speaking, a coagulating ferment; the coagulation being a secondary effect, the result of a change in solubilities. Rennin action is probably a hydrolytic cleavage and may be considered the first step in the proteolysis of casein. It would follow from this that the action now attributed to rennin may be produced by any proteolytic enzyme.

65. **Carbohydrate Feeding and Muscle Creatin.**—The influence of carbohydrate feeding on the creatin content of rabbit muscle, Myers and Fine found, is similar to that observed in starvation, although after a long period of feeding there may be an even greater reduction in the creatin concentration. The decreased elimination of creatin after feeding carbohydrate is primarily dependent on the sparing action of carbohydrate on the muscle protein, or, in other words, is simply one phase of the sparing action of carbohydrate on protein metabolism.

71. **Effects of Pancreatic Extracts on Glycosuria.**—Intravenous infusion of pancreatic extract made from cow's pancreas by Knowlton and Starling's method raised the D:N ratio on the days immediately following, when the urine was collected in twenty-four-hour periods. When the urine was collected in short periods a similar extract produced a slight fall in the hourly dextrose elimination and in the D:N ratio in the hours immediately following injection. A mixed extract made in the same manner from dog's pancreas and duodenal mucosa produced a greater fall and in one instance complete disappearance of the urinary sugar. The fall, however, was followed in three to ten hours by a compensating increase. A similar quantity of Ringer's solution made alkaline to about the same degree as the medium for the extract, produced an effect on the glycosuria almost identical. A 2 per cent. Na_2CO_3 solution likewise caused a sharp decline in the excretion of sugar and a 2 per cent. HCl solution by stomach tube, produced a sharp increase. The increase in the one case continued for about the same length of time as the decrease of the medium on glycogenesis and glycogenolysis. It is possible also that the pancreatic extract affected the renal permeability. Neither extract of pancreas alone nor the double extract of pancreas and duodenal mucosa produced, within the time of maximal effect on the glycosuria, any effect on the respiratory quotient which could be interpreted as an index of increased combustion of carbohydrate. The total energy production of a depancreatized dog was found to be 42 per cent. greater than that of the same dog while normal. Transfusion of 200 grams of normal dog's blood likewise produced no observable effect on the R. Q. of a depancreatized dog. Murlin and Kramer conclude that neither the use of the Knowlton-Starling extract nor the transfusion of normal blood is yet a measure of any practical importance in restoring to the depancreatized dog the ability to burn sugar.

81 *Action of So-Called Emmenagogue Oils on Isolated Uterine Strip. D. I. Macht, Baltimore.

75. **Absorption and Excretion of Ammonia.**—McGuigan claims that traces of ammonia are excreted, and probably absorbed, normally by the lungs. Ammonia and ammonium salts in stronger concentration are readily absorbed and excreted. Absorption is shown by stimulation of the respiration, spasmodic twitching of the muscles and by an increase in the ammonium content of the blood. Excretion is shown by an increase in the ammonium content of the fluid of the lungs.

81. **Action of Emmenagogue Oils.**—The following oils were studied by Macht: *oleum hedeomae* (pennyroyal), *oleum sabinae* (savine), *oleum tanaceti* (tansy), *oleum rutae* (rue), *oleum thymi* (thyme), *oleum terebinthinae* (turpentine), and apiol. Weak solutions or emulsions of these were made up with Locke's solution. Controls were also made with an emulsion of a neutral oil (olive oil). All of the substances used, even in small amounts, exhibited absolutely no stimulating action on the uterus. On the contrary they caused it to relax, and even paralyzed it. Pennyroyal, tansy and apiol were the most toxic of the group. The least deleterious of the oils was turpentine. It was necessary to use stronger emulsions of this drug to obtain the same effect. The paralytic action of the oils studied is exerted not only on the normal uterus, but also on one which is under the influence of a uterine stimulant.

94. **Transfusion of Blood.**—The instrument designed by Freund consists of a well-fitting aspirating syringe, holding 20 c.c., a "two-way" stop-cock irrigator with a glass cylinder attached to this device, and two tubes with needles attached leading from each tube. The glass cylinder is fitted also with a small stop-cock. The whole is mounted on an inclined wooden base, which rests on the table. Into the glass cylinder is poured normal physiologic salt solution a little above body temperature. By opening the stop-cock of the cylinder and drawing out the plunger of the syringe, normal salt solution is taken into the syringe to about 5 c.c. The stop-cock is then closed. Both needles are then held vertically and normal saline washed through them until all air is removed from the rubber tubing and the needles. Four c.c. of normal salt solution still remains in the syringe. The larger needle is then inserted into the median basilic of the donor and fastened there with adhesive. The lever of the stop-cock is turned, permitting of suction to be made from the donor. This shuts off the saline that remains in the tube going to the recipient. Immediately suction is made on the tube in the vein of the recipient and the blood flows into the syringe. From the average vein 16 c.c. may be drawn into the syringe in less than half a minute. The syringe is revolved so as to thoroughly mix the blood and the saline.

As soon as the syringe is filled, a little of the mixture of the blood and saline is injected back into the donor, so as not to leave fresh blood without admixture of saline in the tube. The lever of the stop-cock is then turned toward the recipient, who first receives the saline remaining in the tube and then receives the entire injection of blood. At this point, for safety, if the experiment has not proceeded within the space of three minutes, it is well to wash both the donor's and the recipient's needles and tubes with a little saline solution, which may be obtained by opening the stop-cock from the cylinder and drawing salt solution into the syringe again. This may be done again and again until as much blood is injected as desired. Freund has employed this procedure successfully in seven cases up to the present time. From one individual, a polycythemic patient, he took blood, 160 c.c. in all, and injected into a pernicious anemic. Recently, blood was taken from the jugular vein of a normal rabbit and reinjected into one of the veins of the ear. In all, but 20 c.c. was taken. The purpose was to observe if any change occurred either in the heart or lung from the experiment. The animal was killed at the end of twenty-four hours, and the pathologic examination of the heart and lungs revealed no gross changes, such as might come from the injection of a small clot or particle into the lungs, giving rise to an infarct or pulmonary embolus.

16 Bacteriology of Calf Lymph, at Present Supplied for Vaccination in Sydney. H. Tebbutt.

2. **Unusual Cases of Hydatid Disease.**—The cases cited by O'Hara are: 1. Hydatid at the back of the eye-ball. 2. Hydatid on the brain. 3. Hydatid of the left lung, implicating the pericardium. 4. Spontaneous fracture of the humerus caused by hydatid cyst in the shaft of that bone. 5. Hydatid in the jawbone simulating actinomycosis. 6. Hydatid in the apex of the right pleura simulating aneurysm of innominate artery. 7. Hydatid on the posterior surface of the liver pressing on the head of the pancreas, simulating disease of that gland. 8. Hydatid at the base of the lung, causing laryngitis. O'Hara finds that by means of the Roentgen rays it is now an easy matter to locate pulmonary hydatid cysts, the shadow outline shows so clearly in the lung tissue.

5. **Two Cases Simulating Appendicitis.**—In one of these cases Jackson found no appendix, no cecum and no ascending colon. The ileum appeared to end under the liver, where its junction with the colon was suspended to the upper part of the outer wall of the abdomen by a distinct ligament. From the point of this attachment the colon ran transversely across the abdomen in the usual situation, and was attached to the wall of the abdomen in a similar way to its commencement. Searching in the mesentery in the right hypochondrium for any remains of an appendix, he found two calcified glands; so hard

and angulated was one of them that one could believe easily that the pressure of a neighboring organ would cause considerable pain in that organ. He removed both glands. After the first forty-eight hours the patient was entirely freed from the pain that he had formerly complained of. The removal of the calcified glands seemed to have made that difference to him. Both cecum and appendix were found in the left side. To the inner side of the ascending colon was found the cause of the trouble—a coil of intestine nearly a foot long pushed through a hole (as it appeared) in the mesentery and under a broad band of peritoneal fold, so as to obstruct its circulation.

17. **Chemotherapy.**—What is the exact nature of the problem the chemiotherapist sets out to solve when called in to prescribe for a man or an animal infected with some living parasite—protozoon, trypanosome, spirochete—visible or ultramicroscopic bacterium? The problem is, how to find a drug that will kill the parasites without hurting their host. To kill the parasites in test-tube experiments is easy, and can be done by any one of the many disinfectants and antiseptics in daily use. In the animal body, however, these disinfecting agents show a uniform tendency to attach themselves to and destroy the tissues of the host, leaving the infecting agent comparatively unharmed. To use Ehrlich's terminology, such drugs are organotropic and not parasitotropic. The chemotherapist has, therefore, to make and try a succession of synthetic compounds of such a chemical constitution as his experience shows him are likely to be parasitotropic in a high degree, organotropic as little as possible. Patience, skill, luck and—last, but not least—money—are the four chief factors on which his chances of success depend.

Chemical compounds can only act on the cells (whether the cell-bodies of parasites or the cells of the tissues that build up the human body) to which they are fixed; the only agent that can fix them is chemical affinity. Clearly, then, drugs will only be fixed by the cells that have a definite chemical affinity for them, or, in other words, have a definite chemical relationship to them. Mercury and arsenic are both metals highly poisonous to living protoplasm. But their salts will cease to be poisonous, however much mercury or arsenic they may contain, unless they have unsatisfied chemical affinities that enable them to combine with the living protoplasm, and so get to work on it. The atomic groups of the protoplasm that effect these chemical combinations with drugs are called "chemioreceptors" by Ehrlich; in the case of the drugs, the atomic groups that combine with the protoplasm are called "haptophores"; the atomic groups that exert the toxic action on the protoplasm are called "toxophores." To take the case of salvarsan, whose structural formula is set out by Ehrlich, the trivalent arsenic molecules are the toxophores, the orthoamidophenol groups are the haptophores; the rest of the molecule is therapeutically indifferent.

There are many obstacles in the chemiotherapists's path, and Ehrlich points out a few of them in the course of his address. To begin with, the difficulty of finding a synthetic drug that will kill the parasites without harming the host is enormous. Next, unless the parasites are all slain by a single injection at one fell swoop, the survivors may acquire a degree of immunity to the drug that will enable them and their progeny to live through subsequent injections. Again, the animal organism may contain dead corners, spots to which injected drugs have no means of access, such as the space which is filled by the cerebrospinal fluid; and parasites may be harbored safely there when they are killed throughout the rest of the body by the injection of some parasitotropic drug. A fourth difficulty may lie in this—that the patient unhappily chances to be supersensitive to the drug, by an idiosyncrasy that makes it far more toxic to him than it is to the ordinary individual. Ehrlich indicates the ways in which these and other difficulties are to be vanquished.

Chemiotherapy aims at the cure of infectious diseases by sterilizing the patient and killing the infecting agent in his tissues; what has been somewhat magniloquently termed a *Therapia sterilisans magna* — cure by sterilization on the large scale—is the objective. Should some of the parasites survive the first attempt at their destruction, the chemiotherapist falls back on a *Therapia sterilisans fractionata*, takes two or more bites at the cherry, and kills off the surviving parasites with a second or possibly more injections of his synthetic drug. Frambesia, or yaws, a tropical cutaneous complaint caused by a spirochete, is almost always cured by a single injection of salvarsan. Syphilis is now recognized to be less amenable to the treatment than this; and, though a satisfactory cure by one injection is claimed for a fair percentage of the cases, the syphilitic will generally have to take his sterilization by salvarsan in fractional or fractionated doses. In the human and animal diseases caused by protozoa and spirilla, speaking generally, the results obtained have been extraordinarily successful; Ehrlich believes that the whole host of bacterial infections will be driven into the corner by the chemiotherapist before many years have passed.

18. **Heredity.**—Bateson has examined human pedigrees, and the result of his search soon showed that many of the more definite hereditary diseases and malformations follow one or other of the systems with which Mendelian analysis has familiarized us. The first condition thus recognized to have a simple Mendelian inheritance was the peculiar malformation known as brachydactyly, described in America by Farabee. Another example is congenital cataract, studied by Nettleship. Both these conditions descend as dominants. It is characteristic of them that unaffected members of the families do not transmit. Not having in them the critical element which causes the condition, they cannot pass it on to their posterity. In the human examples the individuals affected are almost always heterozygous, and hence among the children which are born to their marriages with normal persons, we expect the affected and unaffected to be in equal numbers. In regard to the large group of diseases of nervous origin, such as Friedreich's disease, Thomsen's disease, and others, these sources of difficulty are especially serious; and from study of many genealogies Bateson has come to the conclusion that most of them are essentially dominants. Of recessive conditions in man we have less abundant evidence. Inasmuch as they usually appear from the unions of parents both apparently normal, though heterozygous for the condition, their occurrence is rare and sporadic.

The constant intermarriage of families in the valleys of Sweden, Norway and the Alps, Bateson found, gives the best opportunity for the study of this form of descent. Lately also, the American students of genetics have produced evidence making it clear that feeblemindedness has at least one of the marked features of a recessive condition. When both parents are feebleminded they have no normal children. It is nevertheless difficult to regard this condition as a simple recessive, for unions of the feebleminded with normal persons almost always produce some feebleminded children. Other conditions which exhibit a behavior characteristic of recessives are albinism, myoclonus epilepsy and alkaptonuria. They may all appear in the children of normal persons, with special frequency as the result of marriages of related parents, and there can be no reasonable doubt that these conditions are due to the loss of some factor present in normal persons.

Attention is called to a remarkable group of cases in which the appearance of abnormality may almost without doubt be regarded as partially dependent on the conditions to which the soma is subjected. Of these, Bateson mentions in particular some of the congenital abnormalities, such as hallux valgus; and some of the congenital deformities of the joints, as, for example, dislocation of the hip of the radius. In these cases, he says, we meet the curious fact that whereas the condition most usually appears in the offspring of the normal parents, it may, in certain families, be transmitted from parent to offspring as a dominant. The next group of cases is one in which the descent of the abnormality is limited wholly or partially by sex. Of these, the best known examples are those of the descent of color blindness, hemophilia, and one of the forms of nystagmus.

Referring to the descent of various forms of insanity, nothing has been made out with certainty with the exception of hereditary chorea, which behaves as a dominant, and the condition somewhat vaguely described as feeblemindness, which behaves as a recessive. The genetic analysis of insanity is at the present time practically impossible from the fact that the diagnosis of the various forms of insanity is by no means clear, and also from the fact that the conditions of life have obviously much to do with the development of such weaknesses.

36. **Dosimetric Method of Administering Chloroform.**—Since adopting the dosimetric method Buxton has seen fewer complications, and has been enabled to safeguard patients from chloroform collapse. The appearance of a patient after even a prolonged inhalation of chloroform, when a dosimetric method has been employed, is in striking contrast to what is seen when unstinted quantities of the drug have been inhaled. The one is of almost normal color and suffers few after-effects, while the other is pale, drawn, vomits and is collapsed to a greater or less degree. It is the difference between chloroform acting as an anesthetic and chloroform acting as a tissue poison—between anesthesia and toxemia. Buxton's experience is chiefly with the Vernon-Harcourt regulator. Its maximum is 2 per cent.; however, by using an increase tube, an undesirable addition according to Buxton, it is possible to produce 2.5 per cent. or, indeed, any percentage if the inhaler is specially graded for it. Buxton's experience, now extending over nearly ten years, has convinced him that, provided an accurate technic is practiced, 2 per cent. need not be exceeded. Very muscular and very obese subjects take a longer time to go under, and when time is an important matter, as in hospital work, a rapid induction with nitrous oxid and ether preceded by an injection of gr. 1/100 of atropin is often serviceable.

Buxton employs oxygen with the chloroform, not because the patient has any difficulty in breathing, or becomes cyanosed when this inhaler is in use, but because he is convinced that oxygen by maintaining the vigor of the tissues is a safeguard under any form of anesthesia. Oxygen also lessens shock and counteracts the tendency of the tissues to weep when large areas are incised or denuded of their covering. The failure to produce complete anesthesia with a 2 per cent. vapor is usually if not always the result of badly fitting masks or unskilled handling, so that although the machine registers 2 per cent. the actual percentage inhaled falls short of it. The use of a flanged mask lessens the danger of leakage. In some surgical operations deeper narcosis than the third degree— i. e., anesthesia—is called for by the surgeon. When this is so, Buxton finds the use of a dosimetric inhaler more than ever desirable, since the danger zone is entered, and the anesthetist requires a scientific instrument which enables him to control the higher percentage, increasing it at critical points in the operation and lowering it when these are passed. At all events, he knows exactly what percentage he is employing, and retains absolute control of the anesthetic.

It is alleged that dosimetric inhalers introduce an asphyxial element, and, further, that they are inapplicable for many types of operation. These statements, Buxton claims, arise from misapprehension or from lack of experience of the method. Cyanosis does not ever occur as a result of using an inhaler; when it arises it is due to preventable complications such as the faulty position of the patient, allowing fluid or other foreign material to occlude the airways or permitting the jaw to drop. Any of these possibilities may arise whatever method of giving chloroform is in use, and are so well known that any expert anesthetist will foresee and guard against them.

37. **Infection of Urinary Tract by Colon Bacillus.**—In ordinary acute cases, Thomson says, the first indication is always to ensure a free discharge of urine, usually by giving large quantities of fluid drink. If the patient refuses to drink enough, the fluid must be administered through a stomach-tube or by the rectum. The second indication is to see that the bowels move adequately. The best drug for this purpose is probably sodium phosphate, because it helps in the alkalinization of the urine. An occasional dose of calomel is also often beneficial. The other important forms of treatment are: (1) alkalinization of the urine; (2) administration of antiseptics; and (3) the use of serums and vaccines. The aim of the alkaline treatment is to render the urine alkaline, and to keep it so for a week or two after all the pus has disappeared and the signs of uneasiness have ceased. Although Thomson has generally used potassium citrate for this purpose he believes that other alkaline salts would probably prove equally efficacious if given in sufficient quantity. The dose of potassium citrate necessary varies considerably in different cases. The smallest amount which he has ever found successful in a severe case of colipyelitis was 24 gr. (1.55 gm.) in the day, in a girl aged 10 months. Generally one should begin with 60 gr. (3.88 gm.) if the patient is under 2 years old, and it will often be desirable to give double this amount. Occasionally 150 gr. (9.7 gm.) or 180 gr. (11.6 gm.) in the day has to be given before the urine becomes definitely alkaline and the temperature falls. Sometimes large doses set up diarrhea; and when this is the case the neutralizing effect on the urine is necessarily weakened. Occasionally the urine becomes alkaline within a day or two after beginning the treatment; generally in four or five days; rarely six or seven days, but never longer. The effect of the alkaline treatment is best estimated by studying the temperature charts; because, when the fever lessens, the other symptoms practically always improve.

The fact that great benefit follows the alkalinization of the urine in acute cases of *Bacillus coli* infection of the bladder, ureters and pelvis is quite established. How the treatment effects this, however, still requires investigation. Antiseptics given by the mouth may act beneficially in two ways. In the first place they may lessen the infected state of the urine by their bactericidal action in the alimentary canal. In many cases of pyuria from *Bacillus coli* infection a dose of calomel is followed by a distinct temporary improvement. The disinfectant action of the mercury in the intestine apparently improves the state of the urine by lessening the number of bacteria which are leaking into it from the bowel from time to time. Salol, in doses of 2 to 4 grains (0.13-0.26 gm.) three or four times a day, is certainly often helpful. Thomson has found it of most use when given in addition to alkaline treatment, especially in the later stages. Urinary antiseptics, such as hexamethylenamin and its various derivatives, which act directly on the bacteria by liberating formaldehyd in urine, have proved of great value in the treatment of urinary infection by the typhoid bacillus and certain other organisms. They are, however, disappointingly ineffectual in most cases of colon bacillus infection. With the serum treatment Thomson has had no experience. Vaccines he has used in a few cases, but with disappointing results.

39. **Treatment of Hematemesis.**—The ideal hemostatic in these cases in Grünbaum's opinion is epinephrin. He took the drug himself experimentally and found that his blood-pressure was not raised and no detrimental signs or symptoms made themselves evident. After this, large doses were administered to patients suffering from a variety of diseases and also to normal people, and it was found that only when there was adrenal insufficiency did the blood-pressure rise. This happened with such regularity that it occurred to H. D. Rolleston and himself that this rise might be used as a diagnostic sign of adrenal insufficiency. The drug was found to be an energetic vaso-constrictor, which, however, does not lead to general rise of blood-pressure when given by the mouth, but will act locally on the injured vessel through its nerve endings. In addition to this, it is not toxic when given by the mouth, nor does it destroy tissues, and, therefore, does not delay healing. It acts in very dilute solution. For these reasons its action approaches that of the ideal drug. It possesses one disadvantage, namely, it is followed by a reaction; there seems to be dilatation after its action is over. To meet this, small doses must be given at short intervals for a considerable period. Administration three or four times a day is useless; it must be given at short intervals, the longest being an hour, if the reaction is to be avoided and the full benefit of the drug attained.

If epinephrin solution, one part in a thousand, administered in dram doses along with grain doses of neutral calcium chlorid does not lead to the cessation of hemorrhage, further treatment must be considered; among these methods are the lowering of blood-pressure; the administration of normal horse-serum; surgical. Two minims of the tincture of aconite may be administered every half hour, until the heart beat becomes slower than sixty to the minute, or the pressure falls below 90 mm. Hg, or the heart becomes very irregular. In most cases the fall in pressure is rapid. The method of administration must depend on the condition of the patient. It is quite obvious that if the stomach is full of blood it would be futile to place two minims of tincture of aconite in it; on the other hand, hypodermic injection of aconite is very painful, because it stimulates the sensory nerves before it paralyzes them. In any case, tincture could not be used hypodermically, but a dilute solution of aconitin in slightly alkaline normal saline. Occasionally, the tincture of aconite may be added to the saline enemas.

As for horse-serum, Grünbaum claims that the rationale of its action in arresting hemorrhage and healing a gastric ulcer is not satisfying. Physiologic, as well as physical, rest should be aimed at. For the first three or four days, the stomach should be kept empty, and water supplied to the patient in the form of saline rectal enemas. Even the introduction of water into the rectum may lead to a certain amount of movement of the intestine, and possibly of the stomach, but it does not, as far as is known, cause any secretion of hydrochloric acid in the stomach. Water given by the mouth may lead to secretion of hydrochloric acid by the gastric mucosa, and this would tend to dissolve the clot which is acting as a stopper for the ulcerated vessel. Later, when food is given, it should contain alkali and proteid to combine with any acid secreted. Grünbaum is convinced that nutrient enemas in certain cases in which food cannot be given by the mouth for a very considerable time may supply a certain amount of energy.

This is an outline of the treatment of hematemesis when due to acute gastric ulcer. If there is a history of previous attacks of hematemesis, and there is little doubt that it is a chronic ulcer, Grünbaum says the advisability of operation must be considered. It must be remembered that, in all probability, operation will have to be resorted to in the end, and the increased risk of carrying out the operation when the patient has lost blood, and possibly the mouth is in a condition in which operation is not especially favorable, has to be balanced against the risk of the patient dying from hemorrhage. It is not possible to lay down any definite rule; every case has to be considered in detail.

When the hemorrhage is due to some of the other causes, such as duodenal ulcer, the greater part, if not all, of the blood is passed by the bowel. The treatment is in many respects similar to that of gastric ulcer. In malignant ulceration of the stomach, the treatment should be similar to that of chronic ulcer. In cases of hemorrhage due to cirrhosis of the liver, surgical treatment is of no avail, and the administration of hemostatics is useless. An attempt may be made to lower the general blood-pressure, and to increase the coagulability of the blood. Dilatation of the blood-vessels of the liver is indicated, but whether that is brought about by counter irritation of the hepatic region, by means of mustard plasters and the like, is doubtful. The treatment of rupture of an aneurysm into the stomach or esophagues is beyond the medical man. Rupture of an esophageal vein simulates gastric ulcer and is usually diagnosed at operation or post mortem.

55. **Old Fracture of the Patella.**—The details of seventy-eight out of 134 cases are tabulated for comparison of the outcome of different operative procedures in treatment of old fracture of the patella. Even before 1893 the ultimate results were very encouraging, good functional outcome being reported in 72.4 per cent. and 5.2 per cent. with partial use of the joint. Since that date the outcome has been much better, fully 80 per cent. having an extremely satisfactory use of the limb and fairly good in 17 per cent. of the others. Of all the methods that have been applied, the autoplastic technic, utilizing the quadriceps muscle itself, has proved most effectual. Ferraresi described it in 1902; the Murphy, Rotter and Turner technics are practically the same.

56. **Operative Treatment of Pulmonary Tuberculosis.**—Freund's chondrotomy seems to have been abandoned as no reports of its application have been published since 1910. Resection of ribs to mobilize the chest wall is generally regarded as the last operative resort when conditions prevent artificial pneumothorax. The details of 301 cases of the latter are tabulated, with recovery in forty-seven and great improvement in seventy-two. A complete failure was realized in only twenty-five; the procedure can be incriminated for the death of three patients, and thirty-one died from the progress of the disease.

58. **Acute Hemorrhagic Necrosis of the Pancreas.**—Seidel devotes 161 pages to a detailed description of his ten clinical cases and extensive experiments on several dozens of dogs, comparing his results with those of others and adding four pages of bibliographic references. The trouble seems to be the result of activation of the trypsin ferment inside the gland. This activation occurs by way of the pancreatic duct from the action of bacteria or bile or both together, or of enterokinase or of trypsin already activated in the duodenum. Exceptionally, the activation may be the work of bacteria arriving by way of the blood or lymph, or there may be embolism and thrombosis. But under all circumstances, the direct causal agent is the activated trypsin, its action on the parenchyma causing the changes typical of acute necrosis of the pancreas.

60. **Tests of Functional Capacity of the Kidneys.**—Bromberg thinks that the electric conductibility of the urine from each kidney gives the most reliable information in regard to the functional capacity of each, and he gives an illustrated description of the apparatus which he has devised for testing the electric conductibility and commends as simple and accurate. He gives a few examples in which a number of the usual tests were applied and the findings compared. Many of them conflicted with each other but the course of the cases in all confirmed the findings of the electric tests.

64. **Relation between Chronic Inflammation and Ulceration of the Stomach and Gastric Cancer.**—Konjetzny gives an illustrated account of a case of multiple multicentric cancer devoloping in the stomach on a basis of chronic inflammation and polyps. In another case the stomach contained several cancer foci, this multicentric carcinosis having evidently developed on an adenomatous polypous hyperplasia of the mucosa, the transitional phases being apparent at many points. Other cases showing cancerous degeneration of a chronic hard ulcer are illustrated also, while in other cases a secondary ulcer had developed in a stomach already the seat of malignant disease. Without careful microscopic examination it may often be impossible to say whether the ulcer or the cancer is secondary in such cases. In any event, the data presented emphasize anew the extreme importance of inflammatory conditions in the stomach mucosa for the development of gastric cancer. Most dangerous apparently in this respect is the polypous proliferation of the mucosa resulting from chronic gastritis. He thinks that about 10 per cent. of gastric cancers probably develop from an ulcer.

65. **The Menstrual Temperature Curve.**—Hansen reports extensive research to determine the fluctuations in temperature connected with menstruation and pregnancy. He gives three 5-page charts to show the typical temperature curves. Before puberty and after the menopause the temperature runs on a constant level, as in men, with very slight fluctuations, but menstruation brings a temperature wave rising high just before the menses and falling below normal afterward, beginning to rise again about two weeks before the date of the following menstruation. The premenstrual rise in temperature starts to decline one or two days before the onset of the menses. The type in all the women was alike. Hansen compares his findings with those of others and emphasizes their importance. Conditions are liable to mislead in the estimation of the temperature in disease unless the physiologic fluctuations in the temperature are known and allowance made for them. He theorizes to explain the causes for the fluctuations, attributing to exaggeration of metabolism of albumin the rise of temperature observed. It occurs under conditions requiring an increase in the vital processes, as in pregnancy and lactation. One special point which he emphasizes is that during the first third of pregnancy, the temperature is of the high premenstrual type; it falls later and is more of the postmenstrual subnormal type during the last half of pregnancy, with no monthly periodical fluctuations. Another point is that during periods of increased metabolism the interval of metabolic rest—from midnight to early morning—is abbreviated, so that the temperature at 6 a. m., for example, is as high as considerably later in the day under other conditions. And yet the minimal temperature may have persisted the same.

66. **When Should the Lungs be Treated by Compression and When by Exercise?**—Kuhn reiterates that with pulmonary tuberculosis the lung should either be kept entirely at rest or kept actively movable. Any half-way state between active movement and complete collapse is not only irrational but actually promotes the proliferation of the tubercle bacilli. The lung should either be squeezed tight or it should be exercised and trained to the utmost possible expanding power. There is no middle ground between these extremes. The induced pneumothorax answers the first indication when conditions permit. He defines the indications for compression as extensive processes, especially those with a cavity, in all those cases in which the temperature cannot be kept normal under repose or slight exercise. This applies even in the less advanced cases in which bed rest and respiratory exercises send the temperature up a little or it rises spontaneously on slight exercise even after prolonged repose. On the other hand, the active exercise treatment of the lungs is indicated

in all the (not too advanced) cases which do not show permanent fever and in which under cautious breathing exercises the chest can be mobilized and enlarged while the temperature keeps persistently at normal. The exercise treatment is contra-indicated with all acute inflammatory processes, especially large cavities, and in all cases with persisting fever, even in the earliest stages. By far the best means to mobilize, exercise and train the lung, he says, is with the aspiration mask. This permits graduated exercises, carefully adapted to the condition at the time, and it also permits auto-inoculation, to use Wright's expression for forcing into the circulation toxins from the focus in the lungs. With the aspiration mask this is done in a rational manner, he says, under constant control. Freund's chondrotomy, dividing the costal cartilage to mobilize the chest wall, does this in a sudden violent way, entailing traction on the parts, including the focus, and it is thus more or less dangerous. Kuhn gives a number of illustrations to show the symmetrical enlargement of the chest and expansion of the lung under systematic exercises with the aspiration mask. (It was described in The Journal, 1913, LX, 632 and 768.)

He gives microscopic findings which show that in the collapsed lung the larger blood-vessels are still filled with blood, especially the bronchial arteries, thus supplying nourishment for the lungs and permitting the bactericidal action of the blood on the bacilli. The lymph supply is shut off more completely, and hence auto-inoculation is rendered impossible. He thinks that the exercising of the lung with the aspiration mask, or similar valve device to impede the intake of air, has a decided influence in prophylaxis by increasing the vital capacity. He knows of instances in which the mask has been used by young people for years, off and on, and the shape of the chest and its excursions have been favorably modified to an astonishing extent.

70. **Splenomegaly.**—Kraus' patient was a Russian merchant of 62 who for three months had suffered from headache and pains in the limbs, gastric disturbances, anemia, somnolency and depression, and subfebrile temperature; cardiac dyspnea gradually developed, with anasarca at times, and the spleen increased in size until the longest diameter was about 43 cm. The blood findings were those of an aleukemic myeloid leukemia, with suggestion of pernicious anemia, the total leukocytes not above normal, but the number of myelocytes markedly increased, as also of the young forms of the polymorphonuclear cells, while the polymorphonuclears were reduced in numbers. The patient came to Kraus to have his spleen taken out, but Kraus regards splenectomy as very dangerous in leukemia, and he applied merely radiotherapy and benzol. The patient has improved notably under this treatment and the spleen measures now only 30 cm. A peculiar finding in this case was the discovery of cells in the blood which had every appearance of being endothelial cells. Plesch and Lippmann found similar endothelial cells in the pleural effusion of animals rendered experimentally aleukocytic.

Kraus reiterates in conclusion that myeloid leukemia (*Myelose*) can develop either acute or chronic; with mixed cells or myeloblasts; with or without anemia; with increased numbers of the white cells (numerically leukemic) or with subnormal numbers of white cells (aleukemic), and as a diffuse or more isolated affection of the bone marrow, or splenomegaly. There is no longer any excuse for confusing the splenomegaly of leukemia with the splenomegaly of Banti's disease. The latter is benefited by splenectomy but it is directly dangerous in the bone-marrow disease; death has followed in some instances.

71. **Importance of Cardiovascular Symptoms in Diabetic Coma and Its Preceding Stage.**—Ehrmann calls attention anew to his recent statements that diabetic coma is long preceded by a characteristic drop in the blood-pressure due to the toxic action on the cardiovascular system of the beta-oxybutyric acid and the acetic acid. The patient dies in the coma not from sudden heart failure, but from the cumulative toxic action of the butyric acids. He further presents evidence to prove that the beneficial effect of large doses of an alkali in diabetic coma is not due to saturation of the acids but to the fact that the elimination of the toxic acids is materially promoted by the alkali. The ferric chlorid urine test may be negative even in incipient coma, but after administration of the alkali the reaction becomes positive. The patient is in greater danger, the less the response to the ferric chlorid test applied to the urine.

Long before the coma develops, the toxic action of the butyric acids can be detected by watching over the cardiovascular system and, if it shows signs of weakness, coma can be warded off by keeping it up to par with the proper drugs. He insists that just as sodium bicarbonate must be pushed until the urine becomes alkaline or, rather, until the ferric chlorid test elicits the most intensive response, the tonics for the cardiovascular system must be pushed in the same way. He gives the details of eleven cases in which by keeping the cardiovascular system under control he was able to avert impending coma by subcutaneous injection of camphor or caffein or some preparation of digitalis by the mouth. One patient has been in this stage of precoma for two years. This is a man of 42 and he frequently had what Ehrmann calls the "precoma expression," resembling the sleepy phase which follows after an epileptic seizure. The blood-pressure was 140 or 150 mm. After a few months there was a slight attack of coma; then the respiration became deep and slow, twenty to the minute; the eyeballs were soft; the blood-pressure only 100. Subcutaneous injection of camphor tided the patient past the danger point, and full earning capacity was soon restored although he still occasionally has periods of deep costal breathing.

In cases of permanently low blood-pressure, Ehrmann has given caffein sodiobenzoate, 7:200, in daily doses of from three to six tablespoonfuls over long periods without any unfavorable action on the stomach. He prefers this preparation of caffein to the sodiosalicylate, as it does not affect the ferric chlorid test in the urine, like the salicylate. He also advises such patients to drink strong coffee or tea daily. Caffein has further a stimulating effect on the diuresis, independently of the blood-pressure. Together with the caffein, or alone, digitalis may be needed. After the coma has once developed, measures to act on the cardiovascular system may come too late.

73. **Treatment of the Severest Forms of Ataxia in Tabes.**—Frenkel here gives the principles of his method of reeducating the muscles in locomotor ataxia, with the modifications for individual cases. (The Journal has recently summarized some discussions of this principle of analytic compensatory exercises in reeducation of the motor system, as, for example, 1913, LX, 252, 634 and 927.) Frenkel insists that with uncomplicated tabes complete success depends merely on whether the patient is able to devote the necessary time to the course of exercises. With even a small amount of muscle sensibility, the patient can learn to walk in the exercise room with his eyes shut. But this may take a year or longer; even at the best, weeks must pass before the patient has learned

to take the first independent step. The dangerous atony of the bladder and intestine is checked by the exercises keeping the abdominal musculature in healthy action. Severe catarrhal affections of the bladder are extremely rare in patients taking the exercises. The great trouble is the length of the course required. The expense in a private sanatorium is often prohibitive, and public institutions are more to relieve acute sickness. The finest results Frenkel has ever witnessed from the exercises in the severer forms of ataxia were at the Salpêtrière at Paris, which is, to a certain extent, an institution for incurables. A person once admitted to this department cannot be discharged against his will. Frenkel knew of one patient who had been completely cured of the severest form of locomotor ataxia and could walk independently and climb into an omnibus, but he refused to leave and he also refused to do any work in the institution. In Germany the sick benefit societies refuse to pay for such courses for their policy-holders, probably because of the failure of courses as given in the public hospitals, owing to the lack of trained skill or to the shortness of the period of training. Frenkel adds that there are no contra-indications to the exercise treatment properly applied, but he warns explicitly against combining this treatment with a course of baths. Balneotherapy with or following the exercises frequently leads to slight paresis of the muscles of the legs which in a few weeks may develop into total paralysis.

79. **Subphrenic Abscess.**—Ledderhose says that a just preceding appendicitis or liver trouble may give the clue when there are no local subjective or objective signs of the abscess, but merely that the general condition does not improve as rapidly as anticipated and fever drags along after the primary affection is supposedly conquered. Only rarely is the subphrenic abscess ushered in with a chill, high fever and pain. In the subacute cases there may be pain in the intercostal spaces or below the costal arch; the side involved does not share in the breathing excursions as much as usual. Percussion reveals a zone of relative dulness which in front has a cupola-like outline. The liver seems to be pushed down, the heart up. Accumulation of gas in the region is revealed by resonance between the lung and liver, changing its location as the patient changes position. Roentgenoscopy shows the diaphragm abnormally high, and reveals accumulation of gas, but if the pleura is involved the roentgenoscopic findings may be misleading. If exploratory puncture brings pus, the indications for operative treatment are given at once. By introducing and withdrawing the cannula very slowly, there is less danger of missing the abscess; it may be necessary to puncture at several points before the pus is discovered. He is confident that if the space just below the diaphragm is examined more as a routine measure, the findings will clear up many puzzling cases and permit effectual treatment. He reports several cases from his own *experience in which* the subphrenic abscess developed after operative treatment of perforation of a gastric or duodenal ulcer. In the majority of cases the appendix was the *primary seat of* trouble. In differentiating subphrenic abscess, empyema, pyopneumothorax, pulmonary and liver abscess and liver echinococcus cyst are the affections which have to be excluded.

83. **Diagnosis of Incipient Apical Tuberculosis.**—Richter complains that general practitioners as a rule fail to utilize to the utmost the progress which recent years have brought in the diagnosis of apical processes. He cites Pel's remark that certain physicians percuss and auscultate apical tuberculosis in nearly every patient that comes their way, and, what is worse, give them treatment to correspond. Richter deplores in particular the neglect of the aid possible with Krönig's method of extremely light percussion over the apices, outlining with a pencil the findings for comparison. Percussion is generally applied too hard. The *finger or* plessimeter should just rest on the skin, not press on it. This is especially *important* in percussing toward the side. Fixation of the free margin of the lung, not only of the lower margin, may be the earliest sign of a tuberculous process in the lung. Krönig has often found this lack of movability of the free margins as the earliest sign confirming the suspicion of tuberculosis suggested by *the general condition.* The induration of the apex which develops in consequence *of impeded* breathing through the nose is not yet fully understood and differentiated by general practitioners, as a rule; far too often it is erroneously assumed to be a tuberculous process. Richter describes a typical example of this "collapse induration of the apex"; a man of 25, a great smoker, had had part of the turbinate bones resected six years before, but the mucosa was still so hypertrophied that the lumen was almost closed on one side. During the winter he had *had a* protracted bronchitis and then mild influenza with slight fever. Examination after recovery showed infiltration with catarrh of the right apex and there was a little sputum each morning, but the man felt entirely well and the sputum contained no tubercle bacilli. The appetite was good, the pulse normal, and there was no loss in weight but the resonance of the right apex was impaired and the Krönig field of resonance restricted. The margins of the lungs were movable below on both sides. Auscultation showed a little rough vesicular breathing at the right apex with scanty dry murmurs, but the temperature was constantly normal and the breathing pure. If the physician had not known of the old history of impeded nasal breathing in this case, the diagnosis of apical tuberculosis would have been almost certain.

An unusually low, enlarged thyroid may cast a misleading shadow, and Richter emphasizes the necessity for study of the finished roentgenogram instead of trusting merely to the screen. Kreuzfeld's cough phenomenon, namely, the *lightening up* of the shadow of the apex as the individual coughs, which occurs constantly in health, is conspicuously absent in case of a tuberculous process in the apex. This finding alone, Richter thinks, justifies the necessity for the use of the Roentgen rays in differentiation of dubious pulmonary processes.

85. **Typhoid Bacilli Carriers.**—Levy *discusses* the case of a miner who had typhoid at the age of 15 and has been under observation for the last seven years as a chronic "carrier," constantly discharging typhoid bacilli in the urine. Last year an abscess developed in the perineal region which contained typhoid bacilli in pure culture. Of the forty-one bacilli carriers in the Metz region known to the authorities during the last ten years, two were the source of infection of others in five separate years; four in four years; ten in three years; nine in one year and only thirteen had escaped *infecting* others. The miner whose case is reported had caused infection of others in five out of the seven years he had been a carrier, and two others in four out of seven years. The danger of infection of others increases as the carrier lives and works with larger numbers of persons and in places where sanitary conditions are more rudimentary. Carriers with access to water-closets and accustomed to cleanly habits are far less dangerous than miners and others living in unhygienic environments. If the employers are informed that the *man* is a dangerous carrier, this means merely that they will dismiss him and he will seek work where he is not known, keeping

secret his bacilli-scattering propensity. The only solution for the problem of these unhygienic chronic bacilli carriers, Levy thinks, is to provide some means for their work and support with as little infringement on their liberty as possible, but still making it impossible for them to infect others. As the dangerous scatterers are mostly working people, the question of their maintenance would not be very serious if only some small fund for the purpose was available. By providing for the hygienic welfare of the carriers, the harvest of disease and death they are now sowing will die out from lack of seed.

91. **Alcohol in Infectious Diseases.**—Ewald is not a teetotaler yet he has dropped the use of alcohol almost entirely in his medical service and practice, regarding it as absolutely useless in acute and chronic infectious diseases from the standpoint of reducing the temperature or destroying the bacteria or as a hypnotic. Alcohol does not increase the resisting power of the blood but rather reduces it; habitual users of alcohol are attacked by infectious disease just as often and just as severely as those who do not use alcohol, and they ove less resistant than the latter. The use of alcohol as a od is futile in a single dose, and the continued use is directly harmful. As a stomachic, alcohol can be entirely dispensed with; much better results can be obtained from hydrochloric acid and pepsin in proper doses or infusions of condurango, etc. In chronic tuberculosis, egg-nogs and alcoholic drinks breed gastric catarrh and reduce the patient's power of digestion and assimilation instead of promoting it. In severe collapse, toxic or mechanical or from loss of blood, the stimulating effect of alcohol may prove useful, especially as alcohol is practically always accessible in convenient form, but the success of the "temperance hospitals," where not a drop of alcohol is allowed, shows that camphor, strychnin, caffein, etc., in fact answer the purpose equally well if not better. He cites some experimental research and statistics, including some from a large Leipsic sick benefit society which show that pneumonia occurred ten times as often among hard drinkers as among the other policy-holders and was fatal in a like proportion. Articular rheumatism and other infectious diseases occurred nearly twice as often; and some English statistics show nearly twice as many cancers among drinkers as among the non-drinkers. At the same time, Ewald thinks that a judicious use of alcohol to give flavor to a meal is sometimes advisable, particularly in chronic diseases, the benefit from the appetizing, stimulating influence outweighing the deleterious consequences. But even here, he warns, the use of alcohol in this way should *not* be allowed to become a habit but should be only occasionally permitted.

92. **Diuresis.** — Hess discusses the functional relations between the kidneys and other organs which are much more numerous and important than was ever surmised until comparatively lately. It is easy to detect a tendency to dropsy long before there is any edema if we make a practice of weighing every week our patients known to have impaired heart or kidneys. An increased weight indicates retention of water and by keeping the patient in bed a few days the weight drops by several pounds as profuse diuresis sets in. Widal had a patient who had retention of water in this way without edema to a total of 13.2 pounds. The tolerance for retained water varies within wide limits during this antedropsy stage. The diuretics of the purin series, including caffein, act by enlarging the renal artery and thus promoting the blood-supply to the kidney, while at the same time reabsorption of water in the tubules is reduced. It is not necessary to give the drugs in large doses; small doses answer the purpose still better, suspending the drug occasionally for a day or two. The effect is greatest in the parenchymatous and tubular form of kidney disease and least when the vascular part of the kidney is involved. The effect of the diuretic depends naturally on the heart's being functionally capable; stimulation of the heart action may induce diuresis without further measures. Digitalis has a direct diuretic action from its effect on the renal arteries, even in doses far too small to act on the heart itself. The heart tonics and the diuretics may be combined, but there should be ample intervals to avoid fatiguing the diseased epithelium. Abnormally high arterial pressure may be due to contraction of the peripheral vessels alone, or the contraction may affect mainly the splanchnic vessels, the toxic contraction being the result of accumulation of acids. In this "high pressure stasis," a heart tonic, alone or in combination with caffein, may induce profuse diuresis as the heart action improves.

Restriction of salt is useful only when the kidney is unable to eliminate the salt, but restriction of fluids may be beneficial when either the heart or kidney or both are involved in producing the tendency to dropsy. Von Noorden keeps the average intake of fluids down to 1,500 or 2,000 c.c. a day in chronic nephritis, only at rare intervals permitting the patient to drink more copiously. The advantage of thus reducing the work of the heart is obvious, especially in prophylaxis of dropsy. Hess does not keep kidney patients on a milk diet as he regards this as undernourishment, while the milk contains too much salt. Only when the patients with edema are particularly robust, well nourished or corpulent, he follows the Karell diet. The best results with this are attained in the cases in which the dropsy is due to a combination of kidney trouble with arteriosclerotic and myocarditic processes. Karell allows the patient nothing but 200 c.c. of boiled milk four times a day for five or seven days, at 8, 12, 4 and 8, keeping him in bed all the time. Then he allows also one egg a day, at 10 a. m., and later a little zwieback, returning to the ordinary diet the twelfth day after commencing the course, but not allowing more than 800 c.c. of fluid a day for two or four weeks. By the third day there is generally abundant diuresis and great subjective relief without the use of drugs. Drugs afterward also are much more effectual.

96. **Prophylaxis and Treatment of Scarlet Fever and Measles.**—Elgart has been applying eucalyptus oil according to Milne's directions in prophylaxis of scarlet fever and measles. But he did not smear the whole body with it, as Milne does, but had the children wear a bag kept soaked with the oil, thus inhaling the fumes constantly and disseminating the fumes through the room. Milne is house physician at the Barnado homes for boys, and during his thirty years of service over 12,000 boy inmates have passed through his hands. There were 245 cases of scarlet fever and 234 of measles, all imported from without and none starting an epidemic although the children were not isolated but merely smeared from head to heel with the eucalyptus oil twice a day for the first four days and then once a day for six days, while the tonsils were swabbed with 10 per cent. phenol in oil, at first every two hours the first day and then at longer intervals. The swab used was always the size of the patient's thumb. Elgart prefers inhalation of a 30 or 50 per cent. solution of lime (Aq. calcis) to sterilize the throat, instead of the phenol, and has found it equally effective, but he makes a point of having every one coming in contact with the patients or exposed to infection in any way use the inhalations also, and likewise wear the eucalyptus oil amulets. In one ward with seven children, one developed scarlet fever and was isolated; the other children for four weeks were made to inhale the 50 per cent. solution of lime twice a day at first and later once a day and wear the eucalyptus oil bags and none developed scarlet fever. He remarks that the development of the scarlet fever in a child who had been in the (new) hospital for four weeks suggests that ordinary sore

throat cocci may have acquired exceptional virulence for some reason and thus set up the scarlet fever. Milne's technic is based on the assumption that the eucalyptus oil sterilizes the desquamating skin, but Elgart thinks that this is unnecessary if only the receptive organs of the persons liable to become infected are kept sterilized, and he thinks that this is accomplished by keeping the air of the room saturated with the fumes of the eucalyptus oil on the neck bags, supplemented by direct sterilization of the throat, keeping up these measures for six weeks.

His experience confirms further that the eucalyptus oil neck bags are effectual also in prophylaxis of measles; no further cases developed in a ward with eighteen children after two coming down with measles had been isolated and the others kept supplied with the oil amulets. The isolation was maintained only while the bronchitis lasted, about two weeks. Scarcely any of his scarlet fever patients inhaling the solution of lime systematically developed complications, and they were extremely mild and brief. He is convinced that his success sustains his assumption that the acute infectious diseases are spread by inhalation, and that by keeping the inhaling organs of all exposed constantly sterilized with the eucalyptus fumes, the lime water or other effectual disinfectant, the spread of the infection can be prevented, the disease attenuated and the course shortened.

99. Changes in the Conception and Treatment of Enlarged Prostate.—The illustration given of a transverse section of the pelvis with an enlarged prostate, photographed from a frozen section without retouching, supplements the illustrations given in The Journal July 6, 1912, page 8, confirming anew that the prostate proper does not share in the hypertrophy. Kielleuthner reiterates that the prostate proper is squeezed flat and thus forms a sort of capsule around the enlarged adenomatous mass, so that the latter can be shelled out without injury to the prostate proper or the genital organs. This explains why the genital functioning is not affected by the "prostatectomy" if it is done from above, merely lifting out the adenomatous mass and leaving all the parts and organs below intact. Suprapubic prostatectomy is thus a conservative operation as it leaves the prostate, while it is radical as it removes all that is causing trouble and leaves no chance for recurrence He comments particularly on the great advantage of being able to estimate the functional capacity of the kidneys before the operation, saying that for this we have a number of means at our command, the best, perhaps, being the sulphonephthalein test. This is particularly convenient and reliable as it does not depend on subjective impressions as much as other tests.

He reduces the danger of the operation by doing it at two sittings, first making the opening into the bladder and waiting for the astonishing improvement which almost invariably follows when a free outlet for the urine is thus provided. The operation on the prostate then becomes practically free from danger. Recent reports show that the mortality from prostatectomy has dropped from 22 to 10, 8 or 4 per cent. When the adenomatous mass has been shelled out, Freyer prevents bleeding by flushing the region with very hot salt solution; the same effect can be realized with an ice-cold solution. Severe hemorrhage is combatted by tamponing, packing the entire bladder with gauze if need be. General anesthesia should be avoided when possible; with much debility Kielleuthner employs only regional anesthesia with direct anesthetization of the mucosa. He gets the patient up the third or fourth day.

104. Pyemids.—Werther uses Merk's term for the metastatic skin affections which develop in the course of infectious diseases. The pyemids range from mere erythema to pustules, ulcers and necrotic processes. He reviews the literature on the subject and reports four cases all of one type, a hemorrhagic erythema affecting mostly the face and fingers. In one case the pyemia dated from an abortion a year before; in the second case from a septic sore throat first noted nine weeks before. In the third case there was double infection, with tubercle bacilli and the *Streptococcus viridans*. The fourth patient was the only one that recovered; the dermatitis in this case was evidently connected with nephritis, bronchitis and a sinusitis, and it subsided after the sinus had been evacuated; healing was delayed by intercurrent erysipelas. The whole sickness lasted six months. These four patients were women between 18 and 41. In another case the exanthem followed a streptococcus sore throat and involved the whole body; during life the cocci could be cultivated from the blood. In another case the erythema resembled chronic erysipelas; it developed after twelve weeks of nephritis, bronchitis and myocarditis with high intermittent fever. The patient succumbed to suppurative meningitis. The whole trouble probably originated in an old ulceration found in the knee at necropsy. Besides the persisting erysipelatous affection, there were numerous acutely developing small spots and purpura with streptococcus emboli.

105. Tuberculin Treatment of Dispensary Patients.—Hartmann has been much impressed with the good results obtained with minute doses of tuberculin at the tuberculosis dispensary in his charge. He makes the injection between the shoulder blades, starting with 0.000005 c.c., and has the patient go home and stay in bed for the rest of the day, and if there is fever until the temperature is normal. The excellent results are particularly striking, he says, as the patients are poor and their surroundings are often far from favorable for recovery from their tuberculosis.

106. Death after Salvarsan.—Krol's case differs from the usual type of post-salvarsan fatalities. There was no evidence of hemorrhagic encephalitis and no sign of trouble for two weeks. No mercury had been taken at any time. The patient was a tabetic man of 59 with six healthy children. The salvarsan was given mainly to relieve the severe pains in the limbs, which it promptly did each time. As the pains were relieved by the salvarsan and as it seemed to keep the tabes stationary and as the patient pleaded for the injections, he was given seven intravenous injections of the salvarsan in the course of two years. Two weeks after the last injection extensive necrosis developed in the left rectus muscle and the man succumbed in coma in three days. The interval since the last preceding injection was over a year. The dose was 0.6/200 c.c.

107. Protection of the Hands.—Brüning has found that smearing the hands with petrolatum, after they have been scrubbed, rinsed in alcohol and dried, will protect against germs. The microbes are caught in the petrolatum and when the hands are washed in hot water the germs are washed off with it. He uses petrolatum medicated with boric acid, and states that extensive tests have confirmed the efficacy of this simple protection which he regards as a more certain protection than rubber gloves, as gloves are so liable to tear.

Therapie der Gegenwart, Berlin

August, LIV, No. 8, pp. 337-384

108 *Treatment of Syphilis. (Wann müssen wir Syphilitiker behandeln?) H. Schottmüller.

109 Treatment of Stomach Disease. (Fortschritte in der Behandlung der Magenkrankheiten.) G. Klemperer. Commenced in No. 7.

110 *Exophthalmic Goiter. (Diagnostische und therapeutische Bemerkungen zur Basedowschen Krankheit.) J. Hallervorden. Commenced in No. 7.

108. **Treatment of Syphilis.**—Schottmüller comments on the prevalence of syphilis, citing the experience of a number of German clinicians; in his own internal disease service at Hamburg 18.6 per cent. of 1,014 hospital patients were syphilitics, and 40 per cent. of all his patients with heart disease. Oberndorfer found signs of syphilitic disease of the aorta in 7 per cent. of all the cadavers he has examined (Munich). Deneke encountered 200 cases of aortitis in four years, and a syphilitic origin was unmistakable in 80 per cent. of the total. Lenz estimates that 10 per cent. of all the men in the large cities have syphilis. He found syphilitic aortitis in 52 per cent. of all his syphilitic male patients over 30, and Stadler has reported a still higher proportion, 82 per cent.

According to the general experience, Schottmüller says, the really dangerous period, as far as the vascular system is concerned, is the second decade after infection. Aortitis may develop in three or four years but as a rule it does not become manifest until ten years or more have elapsed. It may retrogress; Oberndorfer has encountered instances of apparently healed aortitis in syphilitics, but they are the rare exceptions, and the shriveling that results from the healing process is liable to entail serious clinical consequences as the process generally is located at the aortic valves and at the openings of the coronary arteries into the aorta. In Schottmüller's twenty-two patients, 1908-1910, the course of the aortitis was unfavorable and often fulminating, notwithstanding energetic treatment was systematically applied. Nearly all the persons with syphilitic aortitis die within one or two years after it begins to induce symptoms. But there is a long latent stage and it is during this stage that treatment must be applied to have any efficacy.

It is here, he says, in the early detection of syphilitic vascular trouble, that the Wassermann test has proved of preeminent importance. The reaction was positive in 86 per cent. of fifty-three cases of syphilitic aortitis in his service, even in the earliest stages of the vascular disease; the only negative responses were in syphilitics who had just been taking a vigorous course of treatment. He remarks that even if the progress of science enables us to abort or cure syphilis in its incipient stages, yet there will always be cases in which the infection was not recognized in its early phase, and no treatment was applied; Fournier states that fully 50 per cent. of his patients with syphilis had never been aware that they had the disease. The detection of late syphilis and its treatment will therefore always remain a task for the general practitioner, and it is to him that the infected will look to protect them against the dangers of syphilitic vascular disease and general paresis. Even the most approved and vigorous courses of treatment do not always protect against them later in life, which shows that our present methods of treating syphilis are far from perfect.

The practical conclusion Schottmüller draws from these and other arguments presented are that every person known to have syphilis should be kept under supervision and especially during the second decade should be tested with the Wassermann technic regularly two or three times every year. If the patient does not apply voluntarily to his family physician for the test each time, he must be summoned. The persons with occult syphilis, that is, who are not aware that they have ever had the disease, can be detected only when family physicians and consultants apply the Wassermann test regularly and indiscriminately as a routine measure to all. He remarks that it is simply amazing to note the frequency of positive responses when this is done indiscriminately, especially in life insurance examinations.

When a positive reaction is obtained, specific treatment should be started at once and be kept up until the test gives a negative response. When the test persists positive in spite of all our efforts, the patient can be reassured that the dangers of the tardy phase may be averted although the treatment may have failed to transform the last symptom, namely, the specific response to the biologic test. Treatment with a positive response should be along the general lines for treatment as in the secondary stage. He warns further that clinical symptoms may occur even with a negative reaction, and consequently that examination of the organs should never be neglected. The same principles of frequent repetition of the Wassermann test and treatment based on its findings should be applied when there is suspicion of an inherited syphilitic taint. He has thus obtained excellent results in a number of children of syphilitic parents; they showed no signs of syphilis, beyond the positive reaction, but specific treatment was at once applied and the children have grown up healthy. The easiest way to obtain the forty drops of blood for the test is by drawing the blood from the tip of the finger directly into the centrifuge tube.

110. **Exophthalmic Goiter.**—Hallervorden reviews his experience with 100 cases of exophthalmic goiter. He regards it as a disease of an essentially protracted course; the acute exacerbations seem to be independent morbid entities, but this is not true in fact. They are merely the flaring up into an acute phase of a long dragging affection. The acute phase subsides but leaves usually some symptoms which show the initiated that the disease has merely entered on another stage of latency. It may be roused up anew or for the first time by the mere administration of iodin or by an intercurrent infectious disease; this occurred in thirteen of his hundred cases; by a curetting or extraction of a tooth; by a course of treatment for tapeworm; by a fright or the death of some close relative (eleven cases); by prolonged worry (eighteen cases), and by overwork (ten cases). In only twenty cases the disease progressively developed to the acute phase without some known exciting cause. In no less than twenty-five cases in his experience administration of iodid was, beyond question, responsible for the onset of the acute phase. Periods of physiologic stress, such as puberty, the menopause and pregnancy, afford a special predisposition. In one of his cases the exophthalmic goiter came on apparently for the first time with the first menstruation. The symptoms were so severe that operative treatment was applied with apparently a complete cure. No further symptoms were noted until the woman reached the menopause, when the trouble flared up anew. In ten of Hallervorden's patients the first signs of the disease appeared during the menopause, and in four other cases the long latent affection flared up anew at this period. On account of the frequent nervous symptoms with exophthalmic goiter, psychotherapy should be given a prominent place in treatment. In addition to complete repose, if possible out of doors, the main reliance should be on hydrotherapy, packs and half baths, as advocated by Winternitz. The pulse generally subsided during the packs. Cooling applications were also found useful for the neck and back every day an hour at a time and a coil of tubing to apply cold to the heart when the heart showed much disturbance. Galvanization of the sympathetic nerve never did any good in his experience, nor antithyroid treatment, but arsenic medication never failed. Out of seventy-five patients treated on these principles, fifty-three were materially improved and the improvement has persisted in many for from four to eight years to date. An operation was advised in the others but some refused it and in some of the others even the operation failed to restore the balance between the glands with an internal secretion, so that the improvement did not amount to much. This group includes those with predominantly nervous phenomena and a particularly insidious course, the type which Stern calls "basedowoid." The symptoms in this form of the disease generally prove refractory to both internal and operative measures; there is usually some psychopathic element in this group. A few typical examples are described; in one case the tremor, insomnia, headache and palpitations were very pronounced but there were no sweats, no diarrhea and no appreciable changes in the neck or eyes. Partial thyroidectomy was followed by rather an aggravation of the above symptoms, and fleeting edema developed. In conclusion he

remarks that the cases with a sudden onset with the fully developed syndrome seem to be the most amenable to surgical measures, while the incomplete forms—probably because these come only late to the surgeon—offer little prospect of relief from an operation. The prospects are not much better with internal treatment, he adds. Real permanent benefit from any treatment may be anticipated only when the disease is not of long standing.

120. **Wandering Spleen in Relation to Gynecology and Obstetrics.**—Montuoro has found records of seventy-nine cases of torsion of a wandering spleen to which he adds one from his own experience, all in women. He knows of only three cases in men. In thirteen cases the spleen was removed during a pregnancy or after delivery, and all the women recovered but one who died the sixth day. On the other hand, four of the thirteen women died who required splenectomy for rupture or other injury of the spleen during a pregnancy. The greatest damage from a wandering spleen occurs when it is in direct contact with the genital organs and adhesions develop or it pushes them out of place. The pregnant uterus may compress a wandering spleen and evil result, while splenectomy during a pregnancy has a very good prognosis. The diagnosis of torsion of a wandering spleen is much facilitated if one only bears the possibility of such a lesion in mind when examining a tumor in the genital sphere.

138 The Pathologic Physiology of Athletics. A. Albu.
139 Degeneration of Nuclei of Leukocytes and Lymphocytes. H. Kronberger.

128. **Degenerative Changes in the Kidneys.**—Munk calls attention to the hitherto unsuspected frequency of degenerative changes in the kidneys as modifying the clinical picture. Examination of the urine sediment will suggest the possibility of this: Fat drops and fatty casts in the urine are a sign of fatty degeneration of organs in various forms of cachexia, anemia and diabetes, and are thus important for the prognosis. They may also suggest amyloid degeneration as in severe tuberculosis. Droplets of fat may also indicate the degree of destruction of kidney parenchyma in an acute nephritis. Highly refractile lipoids in the urine sediment, as examined with the polarization microscope, are a reliable sign of some chronic degenerative affection of the kidney and may differentiate such from an acute nephritis. Highly refractile *(Doppeltbrechende)* lipoids are found in secondary contracted kidney consecutive to acute inflammatory nephritis. Also in primary degenerative large white kidney. Also in relatively small amounts in amyloid kidney accompanied by numbers of isotropic fatty casts. Also, although very rarely, in true and arteriosclerotic contracted kidney. Acute parenchymatous syphilitic nephritis is a type of the pure lipoid-degenerative nephrosis, the large white kidney. The article is illustrated.

129. **Anhidrosis and Diabetes Insipidus.**—The man of 32 in the case reported never perspired and when the weather was very hot suffered severely from symptoms showing lack of the normal regulation and radiation of heat. Diabetes insipidus had also developed and an affection of the skin best described as a miliary angiomatosis.

135. **Chronic Pancreatitis.**—Ehrmann and Kruspe here report a second case in which their diagnosis of chronic pancreatitis was confirmed by the findings at operation. In both the cases the gall-bladder was found sound and the jaundice observed must have been due to compression of the bile duct by the swollen head of the pancreas. They reiterate that examination of the stools is indispensable for the diagnosis of chronic pancreatitis; meat and fat are passed undigested and the patient loses weight rapidly on account of the defective utilization of the nourishment ingested. Pressure on the duodenum may cause retention in the stomach. In one of the cases described this occurred in addition to the jaundice from pressure on the bile duct. One of the patients had colic pains in the upper abdomen; the other never had pain. With stasis in the pancreas the diastatic ferment is absorbed and appears in the urine while the diastatic and tryptic ferments disappear from the stools. The metabolic findings in the two cases are given in detail and also in a case of chronic occlusion of the bile duct but no pancreatitis. The cholecystenterotomy answered the desired purpose in each case. It is important after the operation to regulate the diet to permit only foods which do not require the pancreatic ferments for their digestion and assimilation, thus avoiding meat and fat and partaking abundantly of starchy foods, with possibly the addition of some animal pancreas preparation or vegetable ferment.

144 Serious After-Hemorrhage Following Electric Obliteration of Papilloma in the Bladder. (Fall von starker Nachblutung nach Operation eines Blasenpapilloms mittelst Hochfrequenzströmen.) C. Schneider.

140. **Atrophy of the Prostate.**—Caesar reports three operative cases of atrophy of the prostate and the post-mortem findings in a fourth case, the patient a tabetic. In this case

the prostate had actually shriveled entirely away; there was merely a thin pocket-like fold of mucosa, lying like a valve over the outlet of the bladder. The bladder was much dilated and the walls atrophied and thin. In two of the four cases there was a history of gonorrhea; in the others the origin of the trouble was obscure but there had *evidently been a phase* of inflammation at some time. In one case the operation put an end to all trouble; in the others great improvement followed, so that his experience confirms the advantages of operative relief. Casper has stated that there is no residual urine with atrophy of the prostate, mentioning this as an aid in differentiation, but in Caesar's cases this did not apply, there was up to 1,200 c.c. in one, 1,000 in another and 600 c.c. in the third. Differentiation is difficult; it is important to examine the patient as he stands and again in the lithotomy and again in the knee-elbow position, as the palpation findings are so misleading. When practicable he advises to palpate over a hard catheter, or, with both hands, through the rectum and abdomen simultaneously. It is astonishing, he remarks, how folds of mucosa in the chronically inflamed bladder will simulate an enlarged lateral prostate lobe. He endorses Barth's suggestion that during every operation on the prostate careful search should be made for evidence as to the share of gonorrhea in indurative prostatitis and the share of the latter in atrophy of the prostate in later life.

141. **Catheterization of the Ureters.**—Vogel mentions among other suggestions for improved technic that he has found very useful a long linen bag, about 2 cm. wide, in which he keeps the catheter and sterilizes the whole together. The bag is longer than the catheter and the open end projects beyond the tip of the catheter and is tied around with a tape. When the catheter is to be introduced into the cystoscope the tape is untied, the catheter pushed through into the passage in the cystoscope, the bag still covering the exposed part and held tight on it by a spring clip through which the catheter can be pushed farther in without trouble. By this means all direct handling of the catheter itself is avoided.

143. **Multiple Myoma of the Penis.**—A radical operation was done as the diagnosis of cancer seemed certain on account of the extent of the process. But the trouble proved to be merely a benign collection of myomas scattered through the organ and a less mutilating operation might have answered the purpose. If a scrap had been excised beforehand for microscopic examination. a less mutilating operation might have been done.

154 *Injurious Effect on the Heart of Competitive Athletics. (Die chronischen Anstrengungsveränderungen des Herzens.) R. Beck (Vienna).

152. **Injurious Action of Salvarsan on the Kidneys.**—Schlasberg summarizes twenty-seven cases in which administration of salvarsan was *followed* by the appearance of tube-casts in the urine, showing that the arsenic eliminated through the kidneys after intravenous injection of the salvarsan caused irritation on its way through these organs. He examined the urine of eighty patients systematically. In *most cases the tube-casts* were manifest in the urine the day after the intravenous injection; only in a few instances not until a day later. Reexamination two months later showed no signs of tube-casts. When mercury was being given with the salvarsan, the urine contained more tube-casts than otherwise. Experiments on nine rabbits confirmed this deleterious action of salvarsan on the kidneys; it affects principally the epithelium of the convoluted tubules. There is liable to be albuminuria at the same time; this subsides sooner than the tube-casts.

154. **Danger to the Heart in Competitive Athletics.**—Beck insists that all forms of extreme physical effort, all competitive sporting events, rowing, running, swimming, bicycling, etc., for prizes are injurious for the heart. They should be unconditionally done away with as they wreak destruction on the heart of the young. Rationally managed sports, on the other hand, are a great blessing and benefit for our generation.

156. **Primary Actinomycosis of the Skin.**—Holland adds a third to the two cases previously published in Norway of primary invasion of the skin by the actinomyces. His patient was a man of 62, boarded out in the country as a mildly insane ward of the state. He was physically healthy until a superficial process developed on the chest and gradually spread, the man dying of debility the eighth month. Microscopic findings were negative at first, and guinea-pigs inoculated showed no signs of disease. This excluded tuberculosis, and the assumption of actinomycosis was later *confirmed* by the microscope and again at necropsy. The peculiar odor of the pus, a pungent nauseating odor, was characteristic, as also the tenacious gluey consistency of the discharge from the abscesses. No cattle in the neighborhood were known to have been sick for a long time. Perhaps the most peculiar feature of *actinomycotic* lesions is the lack of involvement or invasion of the lymph vessels and nodes. There are no phenomena on the part of the lymphatic system, no enlarged nodes in the vicinity, and no spreading through the lymphatics even when the infection has lasted a long time. Holland has examined the records of over a thousand cases of actinomycosis and found forty-five in which the actinomycosis developed in direct connection with some injury or at the site of an injury. Comparison of these cases shows that the lesion is of pronounced local character and that the incubation may be only a few days in length. In some cases there was an interval of only eight days; the longest interval in this material was six weeks.

THE ADDED RESPONSIBILITY OF THE SURGEON WHEN CALLED ON TO TREAT SURGICAL LESIONS IN THEIR EARLIER STAGES*

JOSEPH COLT BLOODGOOD, M.D.
BALTIMORE

The easier the diagnosis the worse the prognosis. This statement hardly needs further comment or illustration. It is especially true in malignant disease. When the surgeon is able to recognize cancer by its clinical appearance the relative prognosis is bad. Complete operations in this stage yielded 30 per cent. or less of permanent cures.

When the malignant disease cannot be recognized clinically because of its early stage, but is diagnosed at the exploratory incision by its gross appearance, with or without the aid of a frozen section, the prognosis for an ultimate cure is best, provided the complete eradication of the disease immediately follows the exploratory diagnosis. My investigation of the statistics up to date seems to show that the probabilities of a cure are at least 80 per cent. This, of course, varies with the position of the lesion.

If at this exploratory incision, however, the malignancy is not recognized and a piece of the lesion is removed for diagnosis, or even when the entire local lesion is removed with a narrow margin of healthy tissue, and then, later, after the microscopic diagnosis, the complete operation is performed, the probability of a cure is distinctly less than after a complete operation in a later stage when the diagnosis can be made from the clinical symptoms.

From an investigation of the material recorded in the laboratory of the Johns Hopkins Hospital Surgical Clinic, this statement can be made with certainty. So far as my personal experience goes, it is incontrovertible.

We may safely state therefore, that in the earlier stages of surgical lesions the diagnosis is the major part of the surgery; the operation is minor. It is expert and delicate surgery, nevertheless, and the immediate and ultimate results are the best. In this stage treatment is the test of the diagnostic technic.

In the later and latest stages of the surgical disease the diagnosis becomes the minor part, the operative surgery the major, and the results, both immediate and permanent, are worse. Here we have the test of operative technic.

The more one investigates critically the ultimate results of diseases subjected to surgical treatment, the more one becomes impressed with the fact that surgery in the hands of the majority of operators is usually a little behind the disease.

In the early stages the clinical manifestations are so slight, and the lesion seems so insignificant, that even when the diagnosis is correctly made, the relative "favorability" so impresses the surgeon that he is very apt not to do enough. If he unfortunately makes a mistake in diagnosis the result is even worse.

In the later stages of the disease the apparent hopelessness of the condition checks his enthusiasm to be radical, and here again he often fails to accomplish the possible cure.

This investigation of the ultimate results in relation to the stage of the disease, its diagnosis and treatment, demonstrates that there is room for improvement in both. The investigation should have for its object the development of a method of recognition and treatment which will allow a surgeon to be ahead of the disease, and thus increase the number of permanent cures in every stage. There is no doubt that the best opportunity for a cure is in the early stage, but we have sufficient evidence to demonstrate that in later stages more radical procedures properly performed under improved anesthesia and technic have accomplished permanent cures, and there is no reason why these should not be increased in number.

We must not rest satisfied with our results. We must not continue to follow any routine method of diagnosis and treatment, unless it is constantly controlled by the evidence of the ultimate condition of the patient.

How few surgeons in this country really know their immediate mortality, which is evidence most easily obtained. Fewer still have a comprehensive and accurate knowledge of their ultimate results, evidence more difficult and costly to obtain.

METHODS OF DIAGNOSIS

In brief, our available methods of diagnosis are not always employed. The clinician usually neglects laboratory tests; the strictly laboratory diagnostician does not put sufficient stress on the clinical investigation. There is no doubt that in many instances we are handicapped, especially in the early stages of the disease, by an absence of clinical evidence and by lack of an exact laboratory method, and in some cases the exact laboratory method may have an element of danger. For example, in the majority of cases the excision of a small piece for microscopic diagnosis has an element of danger. In malignant disease it seems to increase the probability of dissemination. We may be able to develop a technic which can reduce or eliminate this danger. In my own experience such an exploration should never be done three thousand dollars' worth of treatment, and not one cent's worth of diagnosis. I sent him to the hospital, where all the routine clinical and laboratory investigations were made. Clinically we could get from the patient only the statement as to his epigastric pain and the loss of weight. He denied luetic infection. The only laboratory test that was positive was the Wassermann. He was then given salvarsan. In two weeks the pain disappeared; in one month he had gained 18 pounds.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

* Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

In the past year I have had referred to me three cases diagnosed clinically as sarcoma of bone. These patients had been treated with Coley's serum, but refused amputation. In each case no Wassermann test had been made. In each case I found this reaction to be positive, and the periosteal swellings disappeared under salvarsan.

In 1904 I discussed this subject of the diagnosis of surgical lesions in their earlier stages[3] and presented the question more thoroughly in an address[4] before the Lehigh Valley Medical Association in July, 1911.

I have been impressed for years with the fact that surgical technic has advanced more rapidly than surgical diagnosis, and that surgeons, from their accumulated records, should present to the medical profession the minimum of symptoms of the early stage of surgical diseases in which, although diagnosis is more difficult, the immediate and ultimate results of treatment are best. I called these minimum symptoms of the earlier stages the "medical aspects," because patients seldom, if ever, seek the advice of the surgeon in this stage, but often that of their family physician, who has not been trained to recognize the significance of these symptoms as the beginning of a surgical lesion. If, then, we educate the people to seek advice earlier and the family physician to properly interpret these lesser and apparently insignificant signs of future trouble, the surgeon will be called on more often to treat surgical lesions in their earlier stages, and will be forced to educate himself to meet the new requirements in diagnosis and treatment.

It is quite possible that the people may be educated ahead of the medical profession, but, whether they seek the surgeon's advice directly or are referred to the surgeon by the family physician in this earlier stage, the responsibility of the surgeon will be the same. If the surgeon is not prepared to make the diagnosis accurately and follow it with the appropriate treatment, these enlightened people may be worse off than if they had delayed.

The question is, therefore, Shall the people force the profession, or shall the profession educate itself and be prepared for these added responsibilities?

I am impressed with the belief that those surgeons who have educated themselves best have traveled and visited other surgical clinics most. Every experienced surgeon and every surgical clinic, as a rule, excels in some particular method of diagnosis and treatment. We must therefore learn from each other; reading, of course, is valuable, but visiting other clinics is more valuable.

The family physician and the clinician who does not operate must familiarize themselves with the best methods of diagnosis and treatment, so that they will be able to refer their patients to that surgeon who will give them the best methods and insure them the best immediate and permanent results.

I shall try in the remaining space to illustrate the added responsibility of the surgeon when called on to treat certain definite surgical lesions in definite localities in the earlier stages, and discuss briefly the methods of diagnosis and the treatment which should yield the best immediate and permanent results.

PREPARATION FOR OPERATION

In the so-called acute surgical lesions there is little time for preparation and only time enough for those methods of clinical and laboratory investigation which will indicate what to do. The question to be settled is, Is there any indication for operation? Is the danger of immediate intervention less than of delay? As a matter of fact in this group the usual preparation for operation is not necessary, because the operative intervention relieves the patient of such a burden due to the acute condition that the resultant shock is often insignificant and readily borne. This is well illustrated by the difference in the behavior after operation of a patient with a non-strangulated reducible hernia, and of one with a strangulated hernia; between the convalescence from operation for acute appendicitis and for a chronic appendicitis operated on between attacks.

In acute surgical lesions delay affects chiefly the immediate mortality. The difference in the ultimate result is not so marked in the patients which recover.

The minimum symptoms of an acute surgical lesion which will allow a diagnosis in the stage which gives the best immediate and permanent results, are not such a difficult problem, and have been pretty well settled. The people are fairly well educated, and the family physician is more keen, and the surgeon better and better prepared to give the patient the best chances. This is true in acute appendicitis, in intestinal obstruction, perforation of gastric and duodenal ulcer, abdominal wounds and other acute conditions. There is room, nevertheless, for considerable improvement in the earlier recognition. The added responsibility of the surgeon when called on to treat these lesions in the earlier stage is not so evident. The chief danger is in delay, not in action. Laboratory methods of diagnosis, especially the leukocyte count, gastric lavage and the result of enemas, are often very helpful in the early hours.

In the very earliest stages of acute abdominal lesions physician and surgeons fear chiefly that an operation may be performed when the symptoms are due to a nonoperative condition, such as pneumonia or diaphragmatic pleurisy with abdominal symptoms, acute exanthems of children, or osteomyelitis with abdominal symptoms, etc. These cases are not, however, very frequent, and more deaths are due to delay on account of this fear than to operations based on mistaken diagnosis. Treatment in the late stages of acute abdominal lesions is the test for operative technic, especially anesthesia, which will be discussed later.

In surgical diseases, when there is no danger from delay, there is opportunity to exhaust every method of diagnosis and to employ every well-established preparatory treatment. The earlier the patient is seen and the less distinct the indication, the more elaborate and painstaking should be the investigation and the more careful the preparation. I believe the evidence will show that at the present stage of our development more mistakes are made by hurrying operative intervention in this chronic group, than by delay in the acute group.[5]

[4] Bloodgood, J. C.: Medical Aspects of Surgical Diseases, or Preventive Surgery, The Journal A. M. A., March 23, 1912, p. 829.

[5] Bloodgood, J. C.: Estimation of the Vital Resistance of the Patient, with Reference to the Possibility of Recovery, Ann. Surg., May, 1912; Review on Progress of Surgery, Progr. Med., December, 1912.

It has been my experience that this has been more especially so in patients suffering with symptoms suggesting chronic appendicitis. The patient, the family physician and the surgeon arrive quickly at such a diagnosis; people are so well educated in regard to the dangers of appendicitis that they welcome an excuse to have the appendix out. The preoperative treatment and diagnosis are usually insufficient. The appendix is removed through a small incision. The number of patients not relieved is increasing. The lesions usually overlooked are: some type of gastric and colic ptosis; some lesions of the pelvic organs or vaginal outlet; gastric or duodenal ulcer; chronic infections of the gallbladder; chronic pancreatitis; cancer of the colon, and even renal calculus.

When patients suffering from chronic surgical disease in its earlier stages are really thoroughly studied, the number of mistakes of this kind will be greatly lessened, and by careful preliminary treatment and operation under improved anesthetic technic the number of reoperations will be reduced, the immediate and permanent results improved almost to 100 per cent., and the period of discomfort and disability so shortened that surgery will not be feared as it now is.

ABSTRACT OF DISCUSSION

Dr. A. B. Kanavel, Chicago: One point made by Dr. Bloodgood is well worth consideration, and that is this: When the clinical observations are not borne out by physical examination, we should not of necessity accept the results of the latter. In the present stage of pathologic diagnosis of disease, we are in danger of being too much inclined to depend on a microscopic examination when it is at variance with clinical observation. Clinical observation formed the basis of diagnosis by the older practitioners. In gall-bladder disease there is no need of waiting until the patient has jaundice, when the diagnosis can be made long before the appearance of the jaundice. Why, in appendicitis, wait until the patient has either a general or a local peritonitis? And in ulcer of the stomach or duodenum, why wait for a perforation? We must learn to appreciate the value of an early diagnosis in these cases and that can be done only by having a proper respect for and being able to recognize early symptoms, so that the patient may be sent to the surgeon promptly. The surgeon should teach himself to differentiate medical from surgical lesions, without any relation to which surgical lesion is present, so that he may be prepared to operate on a patient early and not wait for the later symptoms which make the case more severe. In chronic cases particularly, patients are kept waiting for months and even years before they are operated on, and then it is often too late. The greatest difficulty comes in the acute cases of which Dr. Bloodgood spoke. Patients come to us with a typical surgical syndrome; they complain of nausea and vomiting and sudden severe abdominal pain, followed in a few hours by tenderness and rigidity of a portion of the abdomen. It does not matter which particular organ gives rise to that syndrome of symptoms. It means that there is present a severe surgical lesion which demands intervention. It may be an appendicitis, a gangrenous gallbladder, a peritonitis, a duodenal ulcer, a strangulated ovarian cyst, a diverticulitis, or something else, but, no matter what it is, immediate surgical intervention is indicated. To my mind, if the surgeon and physician would recognize this group of symptoms as essentially a surgical syndrome and would impress that fact not only on the patient but also on the general practitioner, the operation would be performed much sooner than it is now, and more patients would be saved. Unfortunately, the necessity for early surgical intervention is not recognized at a time when the greatest good could be accomplished and the result is that the surgeon is called on to treat a complication rather than an early stage of the condition, and the patient's recovery is made more difficult. I urge that this syndrome be recognized as an acute surgical abdominal crisis, a clinical entity demanding surgical intervention.

Dr. A. J. Ochsner, Chicago: We all recognize the splendid work Dr. Bloodgood has been doing in the past in establishing what we might call clinical and pathologic facts. His work has given us a tendency to standardize our views regarding clinical studies of cases, as well as end results. When we have come to the point at which there is great uniformity in our methods of determining a diagnosis, so that we have definite ideas which are almost universal in our profession, then the time will come when we shall make the fewest mistakes. The matter of etiology, pathology and treatment is quite different. Precedent has shown so far that every time in medicine and surgery when we have felt absolutely sure about anything, we have been mistaken. That is exactly what will happen when we have completed our standardization to a degree of uniformity. It is always well to maintain a beneficent distrust of anything that is settled. In Dr. Bloodgood's work, all of these old, well-established facts that everybody took for granted have fallen down. In the future what Dr. Bloodgood is doing and is teaching us to do will come to the same end. As an instance we may take the plan of determining pathologic conditions during the progress of an operation by means of frozen section. In removing a growth, if the pathologist makes his section through the malignant portion, he diagnoses cancer, but if he has made a section through a portion of tissue that does not show cancer, he will make the opposite diagnosis. He may make many sections but miss the portion which contains the nodule of malignancy. If we accept his diagnosis, we do not do the radical operation and the patient suffers as a result of this systematic, well-established and universally accepted method; we must not forget, therefore, the great importance of not trusting any system. I wish to point out one most important thing that Dr. Bloodgood has told us. He has found that wherever there is a superficial cancer it has developed on a previous lesion. That means that cancer is infectious and that in every one of these cases the infection took place at the seat of a previous lesion.

Dr. Frank D. Gray, Jersey City, N. J.: This question deals with responsibility and I should like to call the attention of the surgeons to two kinds of responsibility which they must shoulder. First, there is the responsibility of never operating with a fixed conception of a diagnosis, because you may frequently find that the diagnosis is wrong and that you must do something other than you had planned. You know how frequently that applies to appendicitis. We operate and find a normal appendix. Something must be found to account for symptomatology. Too frequently in the past, and I fear too frequently to-day, many of us were satisfied with the fact that we had operated and found nothing, and we did not try to find the real trouble. I shall mention a case in point: A nurse in one of our hospitals had, for a year, symptoms referable to the stomach. She had vomited persistently. She had pain beginning from an hour to an hour and a half after eating. She said that she had vomited blood. The history was suggestive of gastric ulcer. Stomach analysis did not confirm the suspicion; there was hypoacidity instead of hyperacidity, yet this, of course, did not disprove the diagnosis of cancer. One of the physicians in charge of the case suggested gall-bladder disease. At the same time we both realized that the appendix might be at fault. I operated with the idea that I would find a gastric ulcer, but an incision revealed nothing pathologic in the stomach. I investigated the gall-bladder region, but it, with the common and cystic ducts, was normal. I extended my incision downward far enough to explore the right iliac region and found a pericolic membrane and an appendix which did not look normal. I therefore removed it. Subsequent histologic examination of the appendix showed a chronic appendicitis. The patient had two definite pathologic entities, Jackson's films and a chronic appendicitis. A gall-bladder operation would have been absolutely useless because there was nothing wrong with the gallbladder. The same was true of the stomach.

Then there is our responsibility to prevent infection. I take it that most of the profession depend to-day on iodin to sterilize the field for operation. Up to a year ago I had been in the habit of applying iodin when the patient was placed on the table. Many of my colleagues to-day are using that routine. A year ago I was unfortunate enough to operate in a case of double hernia which became infected on one side. The operation was clean and there seemed at first no reason for the infection. The only way in which I could explain the infection was that the iodin had twenty or thirty minutes longer on the left (infected) than on the right (uninfected) side. I therefore concluded that it was a mistake to operate immediately after applying the iodin; I now apply it twelve hours before operation. In emergency cases requiring immediate operation, we use gasoline for the first cleansing. It is dehydrating as well as cleansing, and is a better preliminary for iodin than soap and water.

Dr. H. C. Sharp, West Baden, Ind.: The leukocyte count is to me a very important additional guide as to the course the surgeon should pursue in acute abdominal conditions, especially that of appendicitis. The surgeon is frequently much in doubt as to whether immediate operation or treatment by the expectant plan offers the best chance to the patient. I have often found that when wavering on that point, the degree of leukocytosis has determined my course of procedure. When I find this acute condition with a leukocyte count of 16,000 or more, I feel well assured that the condition will go to suppuration, and that the wiser thing to do is to operate immediately, while if I find a low leukocyte count, say 10,000 or 12,000, I am reasonably assured that the patient will recover from the acute atack without suppuration, under the Ochsner method of treatment. I do not wish to be understood as advocating that the degree of leukocytosis should determine whether or not to operate in all cases, nor do I even present it to you as an established and unfailing fact that all acute cases of appendicitis, with a leukocyte count over 16,000 will suppurate, and that all cases with a count of 12,000 will not suppurate, but I have found it a valuable indication to assist in determining my procedure.

Dr. Joseph C. Bloodgood, Baltimore: We need more studies on the ultimate results of a large group of cases of the same lesion in which the question of diagnosis in the early stage and the operation which gives the best result should be considered. There are a number of reasons why we do not have that in this country. It is a very great labor and a great expense to consider a group of say five hundred cases and carefully sift the clinical evidence and the operative results. I know that that is true because I have paid for it myself. Nevertheless, we need such studies in this country and until we obtain conclusions based on such investigation we are not prepared for any uniformity in regard to the method of diagnosis and treatment in our cases. I believe with Dr. Ochsner that we must be careful about being definite, but so long as definite conclusions are checked up by the ultimate results, and these results show that diagnosis and treatment along those definite lines give better results, we must follow those lines. There will be an exception to every rule, but that exception in my experience does not injure the rule. We shall probably never reach the stage of exact diagnosis and treatment in every case, but we can improve our results; we must improve our results, if we wish to have patients come for treatment early. I have been so convinced of this that I wrote some friends of mine, asking for money. I said that I wanted to be able in four months to get the results of every case of cancer treated in Johns Hopkins in the last twenty years, and of every case of tumor of which I had a record in the laboratory. The first check to come in was for five hundred dollars, and feeling that more would come I began the work. I have had a group of ten volunteer students and three volunteer patients, and I find that it is going to cost me about four hundred dollars a month for four months. You can see the cost of an investigation of this kind. It seems to me that the clinicians in this country, spending hundreds of thousands of dollars on marble in their operating-rooms, might cut down on the marble and add to the force in the history room. We are not utilizing our medical students as we should. In Baltimore we have medical students who are getting only their board and lodging do this work because it is an education for them. I believe that in the future we shall be able to keep up the results of our work to date by volunteer students, without cost to the university, because the minute a student writes to Jones and Jones writes back that he is all right, that record is of living interest. The student looks at the history, he examines the tissues in the museum and the slides, and he has a record of the fact that John Jones, whose history and specimens show cancer, is well after twenty years. I think that we can get the hospitals which are spending too much money on unnecessary things to give some of it for clerical help to prosecute this study.

ON THE MECHANICS OF PRODUCTION OF CERTAIN FRACTURES

GREENSTICK FRACTURES, BUCKLING FRACTURES, FLEXION AND TORSION FRACTURES [*]

EMMET RIXFORD, M.D.
Professor of Surgery, Leland Stanford Junior University, Department of Medicine
SAN FRANCISCO

Much of the etiology of fractures, particularly from the teacher's point of view, may be presented as an application of the principles of practical mechanics—a part as it were of the subject of the strength of materials in engineering. With their characteristic thoroughness the Germans have given a good deal of attention to the mechanics of the etiology of fractures, particularly to flexion, torsion and perforation fractures, but American surgeons have been too much engrossed in the more practical problems of therapy to devote much attention to the somewhat abstruse mathematical considerations as to how the different forms of fracture happen to be produced, and the text-books used by our students have little to say on the subject.

In the multitudinous forms of accident causing fracture, the bones of the skeleton are subjected to stresses which in the ultimate analysis may be resolved into tensile and compressive stresses. These almost never occur singly but always in combination as in flexion, torsion and shearing stress. Their interrelations may be worked out mathematically and by experiment.

To these must be added shock or vibration, the effect of which in producing rapidly alternating molecular tension and compression is difficult to analyze and to estimate except in so far as shock is a determining factor in time. It is at least a sort of exciting cause, for when a bone is under bending or torsion stress almost to the breaking point, sudden shock or rapid and intense vibration will start the fracture, doubtless modifying its direction to some extent. In gunshot fractures, however, in which the shock or vibration is intensified as a result of the velocity of the impact, this factor is of almost completely determining significance.[1]

Impact at low velocity simply tends to displace the bodies as wholes, which displacement, in the case of the long bones of the skeleton, resolves itself into bending or torsion or both, while impact at high velocity in addition tends to produce local bruising or crushing; hence its penetrating power.

[*] Because of lack of space, this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

[1] Schumacher: Der Mechanismus der Lochfrakturen, Beitr. z. klin. Chir., 1909, lxiii, 81.

The simplest form of stress involved in the production of fracture is simple bending, illustrated in mechanics by the stresses in a beam supported at its two ends and carrying a load between the supports. Compressive stress is developed on the side of the application of the load—a maximum at the particular point of its application—while tensile stress is developed on the opposite side of the beam—a maximum at a point more or less directly opposite. When the load *P* (Fig. 1 *A*) is sufficient the beam will break, the fracture beginning at *T* or *C* according to the properties of the particular material. A cast-iron beam of uniform cross-section will begin to break at *T* where tensile stress is a maximum, while a similar wrought-iron beam will yield by buckling at *C*.

Quite similar are the conditions when a beam is rigidly fixed at one end and made to carry a load at the other. Tensile stress is a maximum at *T* (Fig. 1 *B*) and compressive at *C*.

The shafts of normal adult bones invariably break by yielding to tensile stress rather than to compressive, and in transverse fracture practically always break from simple bending strain as in Fig. 1 *A*, in fracture by direct violence, and as in Fig. 1 *B*, in fracture by indirect or transmitted violence.

The line of fracture is seldom exactly transverse even in a crystalline beam, for in the most rigid beam there is some bending which increases as the line of fracture progresses through the beam, and generally a point is reached at which the cohesion or resistance to the tensile stress in a transverse sense is equal to or less than that in the longitudinal, and the line of fracture takes a more or less oblique direction *a b* or *a c* or both (Fig. 2 *A*). In the latter case a loose fragment is separated off. Note that this loose fragment is on the side of the concavity.

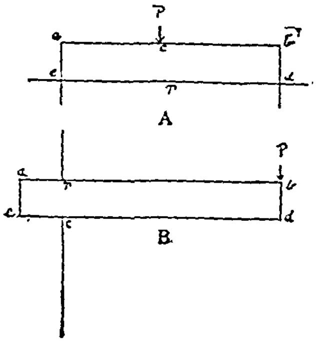

Fig. 1.—Diagrams illustrating *A*, compressive stress; *B*, tensile stress.

In rare cases in which the transverse cohesion is low compared to the longitudinal, simple bending may cause a longitudinal split in the shaft of the bone, the line of fracture at both ends running out on the side of the concavity—the piece broken off is squeezed out, as it were, on that side (Fig. 2 *B*).

While simple bending stress most frequently causes fracture more or less transverse, it may on occasion cause very oblique or longitudinal fractures not only as stated but also as in the case of the femur or the humerus in which the bone is bent inward over a fulcrum on the inner side. The fissure starts between the attachment of the capsule and the trochanter in the case of the femur and the tuberosities in the case of the humerus, and runs down the shaft, generally emerging on the inner side. Such a fracture I have seen which resulted from the use of the Astley Cooper method of reduction of a dislocated humerus, the operator's heel furnishing the fulcrum (Fig. 2 *C*).

In a structure in which there is a definite longitudinal grain as in tough wood subjected to severe bending strain the point *a* (Fig. 2 *A*) is reached before the line of fracture has extended far into the beam, and more or less extensive longitudinal fractures result with bending of the unbroken portions on the side of the concavity; that is, because of the resistance of the broken parts to further bending, they being released from longitudinal tension at the point of fracture, transverse stensile tresses are developed even in advance of the line of fracture and longitudinal fracture results which is often multiple, as in the breaking of a hickory axe-handle (Fig. 3 *A*).

This is precisely the conception of the so-called greenstick fracture; but the lateral cohesion of the shafts of long bones is relatively so large that one would expect this mode of production of incomplete fracture to be rare in children. Yet most of our text-books set forth the greenstick fracture as typical of incomplete fracture in young bones, and of frequent occurrence.

Scudder defines a greenstick fracture as a partial break across the bone with bending at the seat of fracture.

Clinically it is true that fractures with bending occur frequently in children, but it is a question in how far they are of the type described and are properly designated greenstick fractures. My personal observation is to the effect that the true greenstick fracture according to the definition herein given, is the exception among the incomplete fractures in children, which are for the most part buckling fractures, that is fractures by compression, or are complete fractures with splintered ends but with only angular displacement. The only case of greenstick fracture proper which I have seen was in a man of 28, and was of the type illustrated in Fig. 3 *B*.

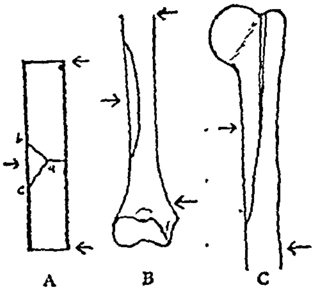

Fig. 2.—*A*, oblique fracture; *B*, longitudinal fracture; *C*, oblique fracture of humerus caused by leverage, in Astley Cooper method of reducing dislocation.

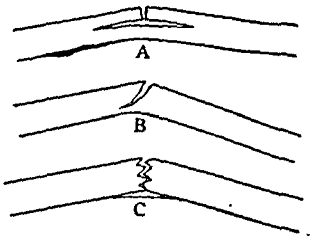

Fig. 3.—*A*, the usual conception of greenstick fracture; *B*, the usual finding in incomplete fracture in young adults; *C*, the usual finding in incomplete fracture of the shafts of bones in children.

Several factors come into play in producing the bent fractures in the long bones of children. The child's weight and strength (important elements in determining the amount of force active in causing many fractures) are small in proportion to the size of the bones in comparison with these relations in the adult. The bones are tough rather than brittle and are surrounded by a much more yielding investiture of periosteum and growing bone than are adult bones, and the greater amount of fat in the child's arm protects the bone from shock.

Transverse fracture with lateral displacement does, however, occur in children if force enough is used, but often in incomplete fractures the force is expended as the tough bone yields and ceases when the bending reaches a certain point short of complete separation of the ends. Under such circumstances the enmeshed jagged splinters offer some resistance to lateral displacement and prevent rotation (Fig. 3 *C* and Fig. 4).

German teachers do not use the term "greenstick" fracture, but account for the bent fractures of children by the looseness and the toughness of the periosteal investiture which stretches and in these cases is supposed not to be torn completely across. Cotton[2] has come to the same conclusion in his paper on subperiosteal fractures in children.

---

[2] Cotton: Boston Med. and Surg. Jour., Nov. 29, 1900, p. 533.

Roentgenoscopy in many so-called greenstick fractures in children after healing has advanced, even when no attempt has been made to reduce the fracture, will show callus on the side of the concavity as well as on the side of greater separation (Fig. 5). This would indicate either that the periosteum is ruptured or that it has been torn up, that bleeding has occurred beneath it and new bone has grown out into the clot.

While the distinction between the conception of greenstick fracture and complete fracture with jagged splinters and only angular deformity may be looked on as merely a quibble, it has this practical significance: It was common teaching to advise that the incomplete fractures in children be made complete in order to restore proper alignment, but some surgeons (Cotton) deprecate this advice on the ground that completing the fracture is unnecessary and increases the difficulty of maintenance of the correct position.

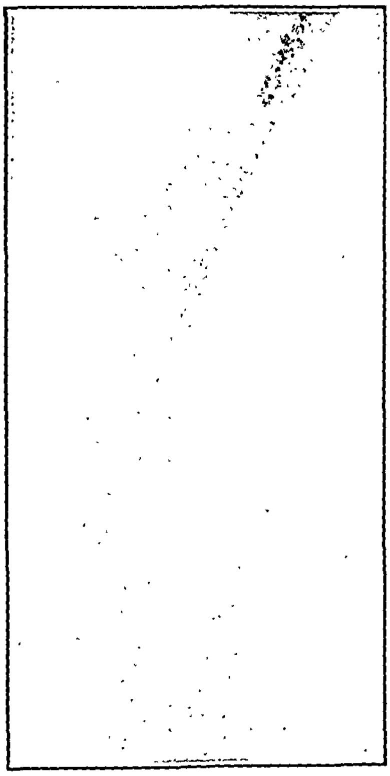

Fig. 4.—Bent fracture of radius and ulna in child of 12.

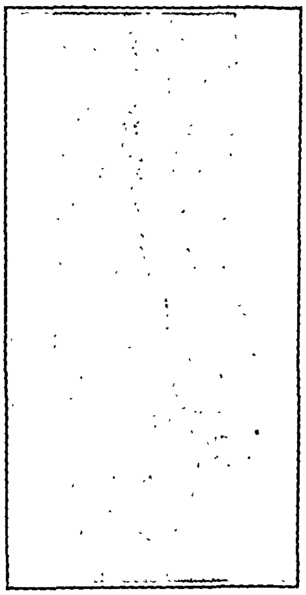

Fig. 6.—Buckling fracture of radius in boy of 8, showing limits of compact bone of the shaft.

For the common form of incomplete fracture of the middle of the shaft of the child's bone, which as said before is really a complete fracture with only angular displacement, simply bending the bones back into place is efficient because there is nothing to break and the soft periosteum will stretch—unless so long a time has elapsed after fracture as to permit of a considerable degree of healing; but perfect reduction in the rare greenstick fracture is almost impossible without completing the fracture, for the reason that reduction requires a certain amount of stretching on the side of the concavity. Therefore, in my opinion, it is proper practice to complete the fracture in such cases by exaggerating the angular deformity present, taking care, however, not to go to the point of tearing apart the periosteum on the side of the concavity, for in general, especially in young bones, the less the periosteum is torn the less opportunity is afforded for the osteoblasts to grow out into the muscles, producing exuberant callus and interfering with subsequent function.

In the long bones of children the medullary canal is smaller than in adults and is especially undeveloped toward the ends. The compact bone of the shaft becomes thin much farther from the ends than in adult bones and the cancellous bone extends correspondingly farther from the epiphyses. In this region, in which incomplete fractures in children's bones are most common, for example, in the radius, the bone, like the wrought-iron beam, breaks by buckling on the side of the compressive stress (Figs. 6, 7 and 8).

Of American text-books on fractures, Hamilton, Stimson, Scudder and Cotton do not so much as mention fracture by buckling.

Of seventeen incomplete fractures of the radius and ulna in children of which we have roentgenograms in Lane Hospital, eight were typical buckling fractures occurring from 1 to 1½ inches above the lower epiphyseal line, half an inch or so below the upper epiphyseal line of the radius, and one was a fracture of the olecranon below its epiphyseal line. Of the eight near the lower end of the radius and ulna, six buckled on the dorsal surface and two on the volar (Fig. 8). The remaining seven were complete fractures with only angular displacement, some of them old enough after fracture and before attempts at reduction were made to show callus, which was quite as marked on the side of the concavity as on the side of the convexity. With the exception of one fracture of the ulna complicating one of the buckling fractures of the radius included above, within 1½ inches of the lower epiphysis, all of these complete fractures with bending were more than 2 inches above the lower epiphyseal line.

While the complete fractures with bending, if taken early, may be reduced by simple bending back into position, the fracture by buckling ordinarily cannot. But the buckling fracture should not be completed by increasing the flexion deformity present as is proper in the true greenstick fracture, but in forcing the bones back into correct position (slight overcorrection is desirable) the bone breaks, beginning at the buckled portion. There is no necessity, however, of so far overcorrecting as to tear the periosteum on the side of the former convexity.

Epiphyseal separation in children as in adults is apparently always the result of tensile stress, the epiphyses being pulled off.

The short bones and epiphyses of young children are almost never broken because of the large amount of cartilage they contain; in adults these bones break by yielding either to compressive or to tensile stress about equally, but, in the matter of relative frequency, individual bones differ from one another. For example, the patella, the olecranon and the lower epiphysis of the humerus are not infrequently broken by being pulled apart, but all three are almost as frequently crushed by direct blows. The os calcis when broken is generally crushed, as is the astragalus and the carpal semilunar.

Shearing stress gives few examples of fracture, yet in the cleavage fracture of the neck of the astragalus, the result of exaggerated flexion at the ankle, the sharp anterior edge of the articular surface of the tibia fairly cuts the head off the astragalus. The body of the bone is crushed and generally pushed out behind the inner malleolus (compare the cherry-stone theory of dislocation of the short bones). The common fracture of the carpal scaphoid may be looked on as of the same sort, but it more probably is a flexion fracture, the styloid of the radius being the fulcrum. From a severe blow on the flexed elbow in line with the shaft of the humerus the olecranon may cleave the humeral condyles apart, or the trochlea may cleave apart the upper end of the ulna.

Of recent years a great deal of interest has centered in the so-called torsion or spiral fractures which we are beginning to realize are far more common than at first supposed. They were formerly classed with oblique fractures, but as the etiology of spiral fractures is better understood and the examples of both are studied, the class of oblique fractures is becoming smaller till it is largely merged in that of spiral fractures.

The long bones are frequently subjected to severe axial torsion, particularly the bones of the lower extremity and the humerus, resulting in typical forms of fracture which are of fascinating interest mechanically and therapeutically.

If a cylinder of approximately uniform constitution be subjected to axial torsion till it breaks, it is found that fracture has occurred in the form of a spiral, the direction of which is invariably the same as the direction of the torsion; that is, if the torsion be to the right (clockwise) the spiral will be a right-handed spiral like an ordinary screw-thread; and, vice versa, if the torsion be to the left the spiral will be left-handed. The fracture is completed by a more or less longitudinal fracture connecting two limbs of the spiral. This may be simply illustrated by twisting axially an ordinary chalk crayon till it breaks.

My attention was first called to the fact that a right-handed twist always produced a right-handed spiral fracture and a left-handed twist always a left-handed spiral by Theodor Kocher in 1899, and later by Dr. Monks of Boston, who made a series of experiments to determine the matter. The mechanics of the production of the spiral was put into graphic or mathematical form by Zuppinger.[3]

Axial torsion develops tensile stress throughout the surface of a cylinder balanced by compressive stress in its interior. When the bone yields to the tensile stress the fissure is propagated along and around the shaft for a long distance in spiral form, and the spiral may encircle the bone two or more times, the bone opening out like a curled shaving from a carpenter's plane. As soon as spiral fracture has occurred, further torsion or unrolling instantly shifts the tensile stresses to the inner surface in a hollow cylinder and the compressive stress to the center. If continued, therefore, the torsion causes longitudinal fracture connecting two of the limbs of the spiral and thereby completing the separation of the two ends of the bone.

In spiral fractures we generally find the spiral running some distance beyond both ends of the fragments (Fig. 9). We also find the periosteum forming a hinge along the longitudinal portion of the fracture in those cases in which there has been no considerable longitudinal force producing shortening; but even in this event the periosteum, though stripped up, is often intact on the side of the vertical part of the fracture, while it is generally completely torn along the spiral part.

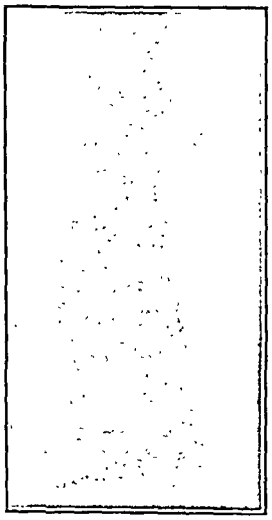

Fig. 7.—Same as Fig. 11, dorsal view, showing lateral spreading of cancellous bone at point of buckling.

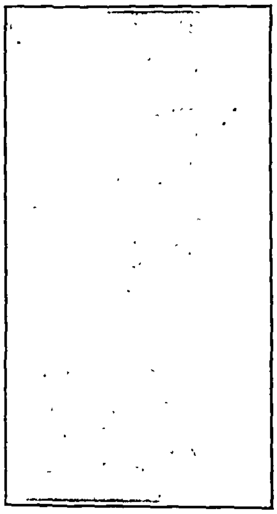

Fig. 8.—Buckling fracture with volar flexion in boy of 11.

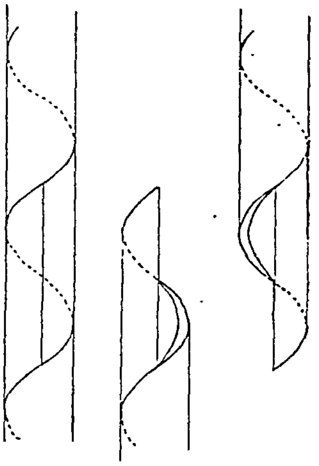

Fig. 9.—Type of spiral fracture before and after separation of fragments.

Theoretically, under torsion stress the entire surface of the shaft of a bone being under tensile stress in parallel spirals, the bone might be expected to break occasionally in two or more parallel spirals. That it ordinarily breaks in but a single long spiral is determined by some weakest point in which the fissure starts, and this is apt to be single. However, it is not at all impossible that search through a large collection of fractured bones might reveal instances of multiple spiral fractures.

Loose fragments which are common in such fractures may sometimes be accounted for by multiple longitudinal fractures, but more often additional bending forces break off one or the other of the long tongues of bone between the spiral and the vertical parts of the fracture.

In actual clinical experience spiral fractures are seldom due to pure torsion, especially in the lower extremities. Weight bearing and sudden muscular effort to escape furnish a severe longitudinal force which, continuing to act after fracture, not only cause the stripping up of the periosteum and furnish the bending stress which breaks off the points of bone or drives them through the muscles and even the skin, but also may be conceived to play some rôle in the production of the fracture in the very beginning, adding a component of longitudinal shearing stress which would have the effect of increasing the pitch of the spiral. Pure spiral fractures are apt to be of higher pitch in young bones than in old, in small bones than in large (Fig. 10).

The vastly greater frequency of left-handed spiral fractures in the right lower extremity and of right-handed spirals in the left lower extremity has been tentatively accounted for on the basis of a spiral grain in the bones resulting from the internal rotation of the lower extremities in the process of development, to which Fleming called attention. In case this internal rotation is inhibited, as in the sympus or siren deformity, the toes invariably point backward. It is obvious enough that as between the upper and lower extremities the latter extremity has a relative rotation of 180 degrees internally, the flexor surfaces being behind instead of in front.

It would require exhaustive experiment to measure the relative resistance of living bones to internal and external rotation, but it would seem that the before-mentioned frequency of left-handed spiral fractures in the right lower extremity, and vice versa, might be efficiently accounted for by the greater frequency of exposure of the legs to external rotation. Most of such spiral fractures occur as the result of twists of the body, the foot being fixed. Since the foot projects forward or forward and outward it is more exposed to external rotation than to internal, for the other leg is in the way of internal rotation. Furthermore, left-handed spiral fractures are relatively quite as common in the right upper extremity which has not undergone the 180 degrees of internal rotation.

---

[3] Zuppinger: Beitr. z. klin. Chir., 1906, lii, 301, and 1909, lxii, 562.

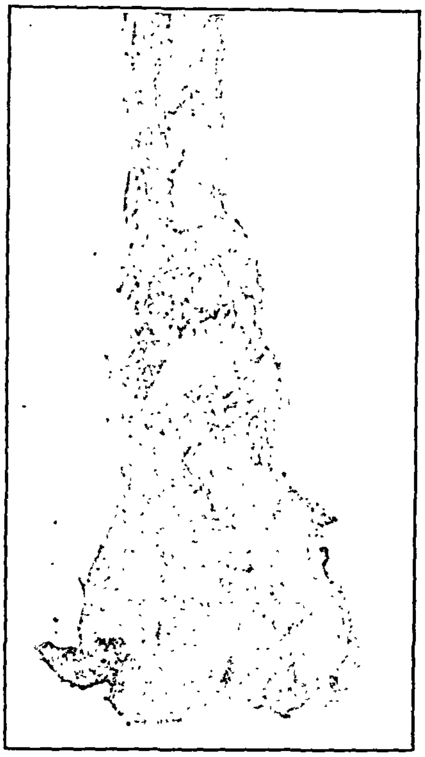

Fig. 13.—Experimental spiral fracture (right-handed) in right femur, periosteal hinge along longitudinal portion of fracture.

Fig. 11 is a roentgenogram of a right-handed spiral fracture of the left femur caused by muscular action on the occasion of the receipt of a bullet in the external condyle of the femur, and Figure 12 is a roentgenogram of a left-handed spiral fracture of the right humerus resulting from throwing a baseball. The spiral went more than twice around the bone. The fracture in the latter case being a pure torsion fracture had no longitudinal displacement, but operative reposition was required because of the entrance of a mass of muscle between the fragments. In another case a burglar running through a sand lot was shot in the right leg. The foot being fixed in the sand inhibited internal rotation as the man jumped and a left-handed spiral fracture resulted.

The right femur may be broken in a right-handed spiral by a right-handed twist as is shown in Figure 13, the result of an experiment on the dead bone with periosteum intact. The periosteum is torn almost the whole length of the spiral but makes a hinge along the vertical part of the fracture, which in this case was on the side opposite the linea aspera.

In the upper extremity the projection forward of the flexed forearm, which is the lever producing most of the spiral fractures of the humerus, effectually prevents internal rotation to the point of fracture by striking the body except when the arm is raised far from the side.

Torsion fracture of the fibula is less common than of the tibia, for often in torsion fracture of the tibia the weight of the body being borne by the fibula off center produces a flexion fracture; still if pure torsion be continued after the tibia has broken, spiral fracture of the fibula will be produced. Spiral fracture of the fibula does not occur without fracture of the tibia except of the external malleolus, which is not infrequently broken in a right-handed spiral on the left leg and left-handed spiral on the right leg, the force being an external rotation of the foot.

I would close with a plea that in presenting the subject of fractures to a class of students the matter be looked on in the beginning from the point of view of mechanics. Experimental study should be given to the manner of breaking of plaster, clay, wood, old rubber, dead human bone and, since living bone breaks differently from dead bone, bone freshly removed from recently killed laboratory animals.

1795 California Street.

ROENTGENOSCOPY OF THE LIVER AND BILIARY PASSAGES WITH SPECIAL REFERENCE TO GALL-STONES *

JAMES T. CASE, M.D.
Roentgenologist to the Battle Creek Sanitarium, Battle Creek, Mich.; and to St. Luke's Hospital, Chicago
BATTLE CREEK, MICH.

It seems timely to emphasize the possibilities of soft tissue roentgenography in the recognition of diseases in the right upper quadrant of the abdomen. The purpose of this paper is to call attention to a number of facts concerning the biliary tract, and particularly the gallbladder, obtainable with the aid of the Roentgen-ray. I wish to preface my remarks by insisting on the necessity of a careful history and a thorough physical and laboratory examination of the patient by the other older-established methods before a correct estimate can be placed on the roentgen findings.

The liver, being opaque to the Roentgen ray and surrounded by more or less transparent organs, permits a study of changes in its position, its size and its shape—often contributory evidence of considerable value. The outline of the upper border of the liver is easily determined. Roentgenographically speaking, the diaphragm is inseparable from the normal liver, their shadows being one, forming the so-called phrenohepatic shadow. The brightly illuminated pulmonary field presents a sharp contrast to the general gray dimness of the abdomen, permitting the upper border of the liver to be accurately studied. One may recognize even slight irregularities in its contour. In a number of cases, a nodular condition of the liver, later verified by operation or necropsy, was determined by a study of the phrenohepatic shadow.

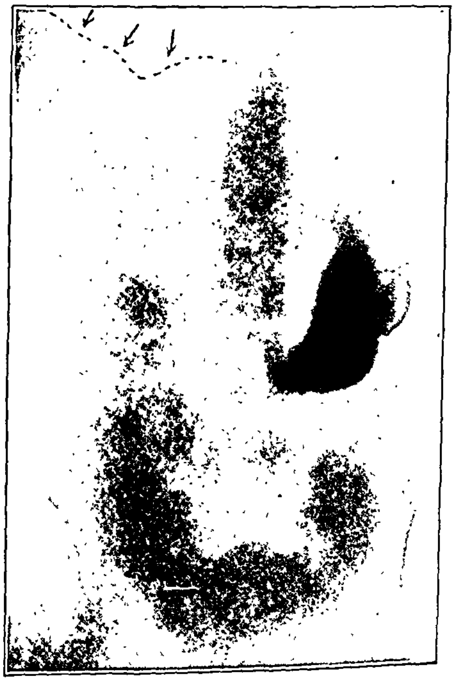

Fig. 3.—Secondary carcinoma of the stomach. Six gall-stones present. Note the irregularity of the phrenohepatic shadow, contributing to the diagnosis of metastatic secondary carcinoma of the liver.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

* Owing to lack of space, this article is here abbreviated by omission of the details of technic, which appear in full in the Transactions of the Section and in the author's reprints. A copy of the latter will be sent by the author on request.

The shadow of the inferior surface of the liver, however, is not so easily determined, being confused with the image of a number of organs—the right kidney, the duodenum and the great vessels, and probably also the colon. In order to emphasize the inferior border of the liver shadow, distention of the colon or stomach or both by means of gas may be practiced. The colon is frequently found already distended by gas collections or it may be artificially distended through the rectal injection of air. Inflation of the stomach may be secured by giving first a solution of 4 gm. of sodium bicarbonate in a quarter of a glass of water, followed immediately by a slightly smaller amount of tartaric acid in an equal quantity of water. Except in special studies, it is rarely necessary to practice this maneuver. In the majority of roentgenograms of the bismuth-filled stomach and colon, the inferior border of the liver, at least its lower two-thirds, is distinctly outlined.

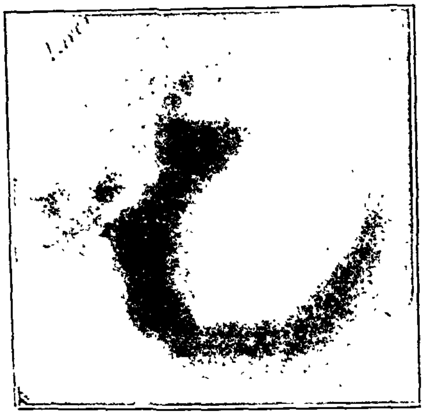

Fig. 4.—Bismuth and gas filled the colon, emphasizing the shadow of the lower border of the liver. Colon adhesions in the gall-bladder region.

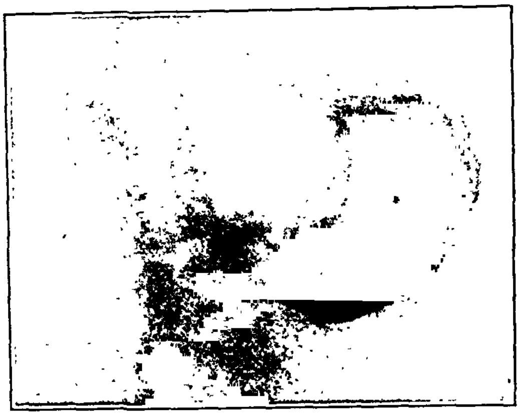

Fig. 5.—Lesser curvature of the stomach distorted by enlarged left lobe of the liver. On fluoroscopic examination peristaltic waves were distinctly seen, proving the tumor to be extraventricular.

Normally the diaphragm and the liver are inseparable. When the shadow of the diaphragm is separated from the liver by an area of clear or transparent tissue, the appearance is very suggestive of abscess. Occasionally a case may be encountered in which an abnormal position of the transverse colon gives rise to a change in the percussion note, which together with the roentgenographic appearances, may lead to the diagnosis of hepatic abscess. Further investigation may show an abnormally long mesocolon, permitting unusual mobility of the colon so that it rises above the superior surface of the liver. The possibility was first described by Chilaiditi, who reported several cases.

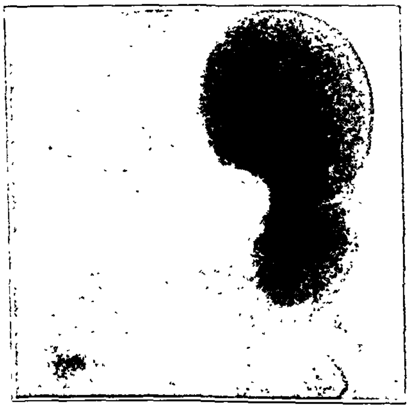

Fig. 6.—Lesser curvature of the stomach deformed by a carcinoma of the lesser curvature. Repeated plate and fluoroscopic examinations showed no peristaltic waves.

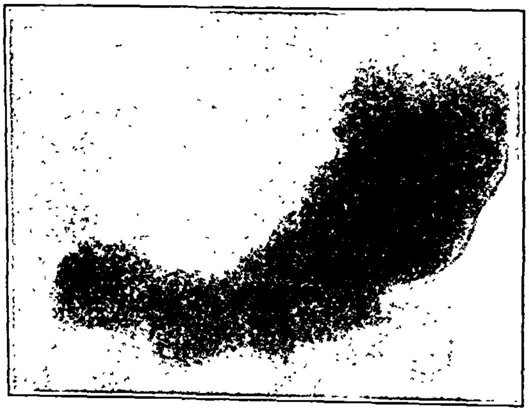

Fig. 7.—Hepatofixation of the stomach, the pylorus being drawn upward and to the right by adhesions due to gall-bladder disease. Two gall-stones present in this case.

Roentgenographic study of the liver is especially valuable in the location of abscess on the posterior or superior surface of the liver. Only in the most extraordinary cases is the Roentgen ray likely to give information concerning abscess in the lower portion of the liver, the abscess extending downward instead of upward toward the lung.

Among the appearances suggesting subphrenic abscess are the following: 1. Diaphragm movements limited and painful, with resulting immobilization of the liver. The other portion of the diaphragm, usually the left, varies its position as usual, or is perhaps more free, in a compensatory manner. 2. The contour of the upper surface of the diaphragm projects unusually high into the clear zone of the lungs. 3. Pulmonary involvement may be seen, the result of infection or rupture. 4. If gas is present in the abscess, the level of the fluid will be discernible beneath the diaphragm, the surface of the fluid remaining horizontal regardless of the position of the patient.

In nodular carcinoma of the liver, relatively satisfactory results are obtained with the Roentgen ray. Roentgen study of the patient in an oblique, posterior position, may also determine the presence or absence of enlarged lymph-nodes of the mediastinum. Following the removal of a tumor of such a nature that the occurrence of metastases is feared, systematic roentgenoscopy may give accurate information as to the location of metastatic foci.

Occasionally a bismuth meal examination reveals a deformity of the lesser curvature of the stomach, when it is necessary to differentiate a lesser curvature tumor from pressure of the border of the enlarged liver. In such instances, determination of the presence or absence of peristaltic waves on the lesser curvature through fluoroscopy or serial roentgenography will permit the differentiation.

ROENTGENOGRAPHIC EVIDENCES OF GALL-STONES AND CHOLECYSTITIS

It has been generally understood for a number of years that it was scarcely worth while to submit a patient to Roentgen examination for gall-stones. This belief was founded on the fact that the principal constituent of gall-stones is cholesterin and that many gall-stones consist almost entirely of pure cholesterin. The experience of Carl Beck of New York only served to confirm this idea. Furthermore, the comparative infrequency with which gall-stones have been discovered in many thousand routine examinations of the urinary tract, as compared with the estimated frequency of gall-stones, according to necropsy statistics, has further served to discourage roentgenographic search for them.

Good authorities, such as Naunyn, have asserted that gall-stones are present in 10 per cent. of individuals. W. J. Mayo, in commenting on these statistics, calls attention to the fact that these high percentages have been obtained by post-mortem material from large hospitals, old ladies' homes, almshouses, etc., and that the illnesses or disabilities which brought these people to the hospitals were, in themselves, "sufficient to bring about gall-stones or to be caused by such disease." Mayo concludes that 0.5 per cent. would be a fair estimate of the frequency of gall-stones in persons of all ages; that 5 per cent. to 8 per cent. of women and 2 per cent. to 4 per cent. of men have gall-stones after the age of 50.

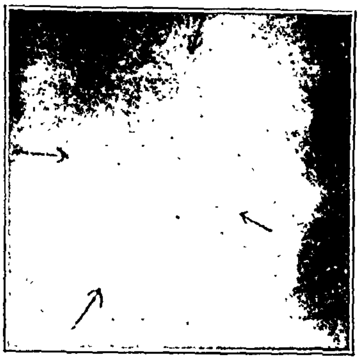

Fig. 8.—Four large gall-stones. Note the capsule-like shadow characteristic of certain gall-stones.

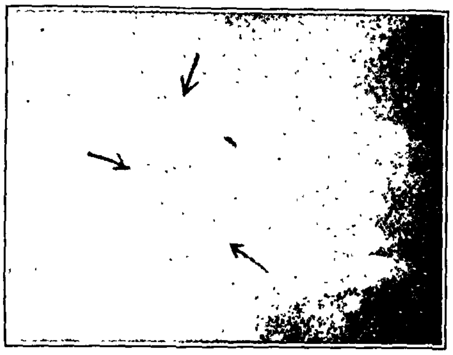

Fig. 9.—Thirteen gall-stones.

In my last thousand cases for examination of the gastro-intestinal tract following the bismuth meal, including a number of cases suspected of cholelithiasis, gall-stones have been identified, roentgenographically, in forty cases. In eight other cases, not examined with bismuth, roentgenograms of gall-stones have been obtained. The large number of gall-stone examinations in connection with the bismuth meal is accounted for by the fact that I do not recommend mere Roentgen examination of the gall-bladder region when searching for stones, but insist that the bismuth examination of the stomach, at least, and preferably of the stomach and bowel, should be included as a part of the Roentgen examination of the gall-bladder.

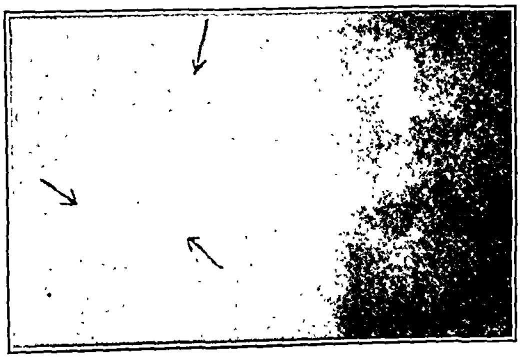

Fig. 10.—Six gall-stones.

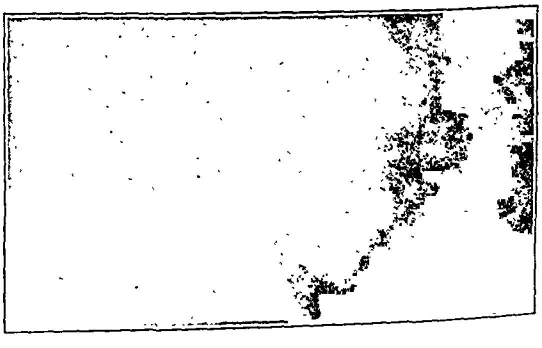

Fig. 11—Six gall-stones.

As before remarked, in a thousand patients referrred for gastro-intestinal disorders, I have demonstrated gall-stones by means of roentgenoscopy in almost 5 per cent. I believe I am safe in the opinion that, when gall-stones are present, they may be demonstrated by this means in 40 or 50 per cent. of cases. A negative opinion as to the presence of gall-stones following the Roentgen examination, of course, does not rule them out, but they are demonstrated with such great frequency that it is distinctly worth while to search for them in every suspected case. This is certainly a larger percentage of gall-stones relatively impermeable to the Roentgen ray than would be expected from our previous conception of the visibility of gall-stones. Pfahler's experience in the roentgenographic search for gall-stones has been equally encouraging.

The increase in the number of cases in which gall-stones have been demonstrated by roentgenoscopy may be explained as follows:

1. Roentgenographic technic of to-day has made great advance, especially with reference to soft tissue detail. This is especially noticeable when intensifying screens are used, although in some instances, a clearer outline of gall-stones has been obtained on ordinary plates made without screen.

2. During a bismuth meal examination, the plate is usually anterior to the body and the tube behind, thus bringing the gall-stones nearer the plate on which their shadow is thrown and thereby increasing the probability of the shadow being recognized. On the other hand, during the usual examination for urinary stone, the plate is placed posteriorly, the tube being in front. In a number of instances it has been impossible to record a recognizable shadow of gall-stones on the plate made in a position for kidney examination, although on the plate placed anteriorly, the shadow was definitely seen.

3. One of the chief reasons for the more frequent discovery of gall-stones, roentgenographically, has been the fact that it has been considered distinctly worth while to look for them, and all plates of the hepatic region are most carefully scrutinized for any suspicious shadows.

4. Recent investigations have shown that it is rare to find stones composed of pure cholesterin on the one hand or of pure pigment salts on the other. The cholesterin stones "nearly always contain some pigment," most likely a calcium salt, and although nearly all gall-stones contain a good deal of cholesterin, calcium salts or bile pigments may be said to be almost invariably present. In the opinion of Dr. Williams,[1] calcium carbonate will be shown to be present much more frequently than has hitherto been thought. Dr. Williams concludes that "for a fuller understanding of the clinical aspect of gall-stones, the usually accepted classification of single cholesterin stones and multiple pigment stones needs considerable modification."

Suspicious shadows, when found, must be identified by various maneuvers to differentiate gall-stones from the various shadows with which they may be confused. Suspicious right upper quadrant shadows most likely to be confused with gall-stone shadows are those due to

---

[1] Williams, O. T.: Quoted by Dr. Thurston Holland; Arch. Roentg. Ray, March, 1913.

(1) calcareous deposits in the costal cartilages; (2) renal calculi; (3) calcareous deposits in a tuberculous kidney; (4) calcified mesenteric lymph-nodes.

Calcareous deposits in the costal arch are easily identified in stereoscopic plates as they are also easily recognizable in plates made postero-anteriorly.

Kidney stones may be identified by their clean-cut edges, their immobility, the homogeneous nature of the shadow and the fact that the shadow of the stone shows within the shadow of the kidney, although several plates may be made in different directions. A comparison of the exact size of the shadows made on two plates, one made anteroposteriorly and one made postero-anteriorly, shows that the shadow of the gall-stone is usually more clean-cut and distinct and somewhat smaller in the latter than in the former.

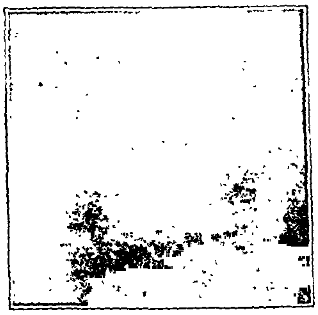

Fig. 12.—A single gall-stone.

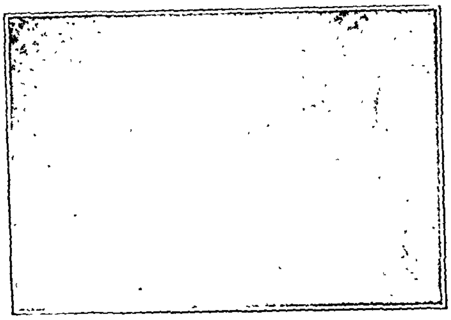

Fig. 13.—Ten gall-stones. This case illustrates the necessity of differentiating from renal calculi, for here the gall-stone shadows are superimposed on the *well-defined shadow* of the right kidney. Roentgenograms made obliquely or stereoscopically are needed.

Pyelography is likely to be of special use in differentiating renal shadows. The shadow of the renal pelvis and the suspected shadow may coincide and several plates at varying angles should be made or else stereoroentgenograms secured, showing that the suspected shadow really rests an inch or more anterior to the renal pelvis shadow. Stereoscopic plates of the renal and gall-bladder region may alone suffice to identify shadows either biliary or renal. E. W. Caldwell was probably the first to apply the stereoscopic method to the identification and differentiation of suspicious shadows in the region of the kidney.

Calcareous lymph-nodes are fairly common, but, as a rule, cast a very characteristic shadow, irregular, the edges being indistinctly outlined, with here and there areas of greater density, giving more or less of a mulberry appearance to the shadow. Calcareous lymph-nodes are frequently multiple and may be demonstrated to be perfectly freely movable by manipulation under the fluorescent screen, or by making plates with varying pressure applied in different ways on the abdomen.

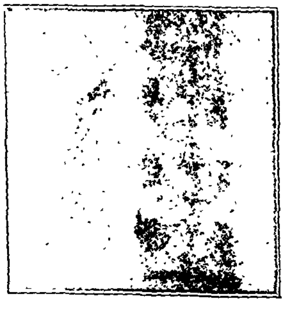

Fig. 14.—More than seventy gall-stones. One in the common duct.

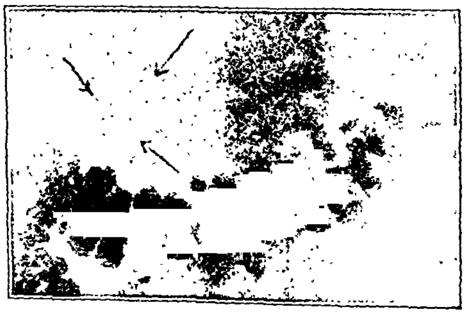

Fig. 15.—Twenty-seven gall-stones.

Identification of hepatic or common duct stones by means of the Roentgen ray has been successfully accomplished by Beck and Pfahler, at least, and perhaps others. I have had one remarkable case of common duct stone successfully demonstrated roentgenographically (Fig. 14).

Many gall-bladder region shadows have characteristic markings which serve to identify them as gall-stones. In visible gall-stones, the calcareous deposits are arranged in strata, usually a calcareous deposit on the exterior, the center being less opaque. The stone thus may present a definite capsule-like circumference. Many gall-stones show facets; others are uniformly opaque. In stereoroentgenograms of the abdomen, the gall-bladder shadows are seen to lie in a plane considerably anterior to the position of the vertebrae and considerably anterior to the outline of the kidney itself. This conception may be further corrected and verified by stereoroentgenograms following the injection of collargol or a catheter into the pelvis of the kidney. It is also likely that stereoroentgenograms following the ingestion of a bismuth meal will show the relation of the suspected shadow to the pyloroduodenal shadow in a manner further serving to identify this shadow as gall-stone.

Under the fluorescent screen, one may often very satisfactorily study the relation of the suspicious shadow to a point of pain on pressure under the right costal arch. Of particular value is palpation following the bismuth meal, when one may find that there is definite localized pain on pressure at a point to the outer side of the duodenal shadow, moving up and down during respiration, whereas on accurate palpation on the gastric side of the duodenal bulb, no pain at all may be present.

Even if no suspicious shadows be present, a number of Roentgen-ray findings following a bismuth meal are of assistance in the diagnosis of gall-bladder disease, with or without stone, namely:

1. Hepatofixation of the stomach, the pyloric region being drawn to the right and upward in a significant manner. Pfahler called attention to this sign two years ago. These adhesions rarely produce delayed emptying of the stomach.

2. A definitely tender spot of pain on pressure accurately localized to the outer side of the shadow of the duodenum. If the duodenal shadow is not sufficiently dense, it may be rendered so by the simple expedient of having the patient lie on the right side for a few moments, and then asking him to turn on the back while holding a full breath. The screen having been in readiness, the current is started, and fluoroscopic study made at once while the pyloroduodenal region is well seen. Or with the palpating hand or a wooden spoon, some of the contents of the stomach can be forced out through the pylorus into the duodenum. It is a characteristic of such cases that there is a lag in the emptying of the duodenum.

3. The presence of Riedel's lobe of the liver, when demonstrable following gas distention of the stomach and colon, is another contributory sign of gall-bladder disease. Particularly in cases of suspected gall-bladder

disease, in which jaundice is not present this sign may be of special value. In several instances I have seen a rounded, localized enlargement on the inferior border of the liver, which proved to be an enlarged gall-bladder.

4. The hepatic flexure of the colon may occupy an unusually high position, a further suggestion of gall-bladder disease.

5. The emptying time of the stomach following a bismuth test-meal is usually much shortened, and the outline of the duodenum is well seen owing to a delay in the emptying time of the duodenum or to a too rapid outpouring of the stomach contents through the duodenum. It was formerly supposed that this unusual visibility of the duodenum strongly suggested duodenal ulcer, but in my experience it may occur in any duodenal affection or in gall-bladder disease.

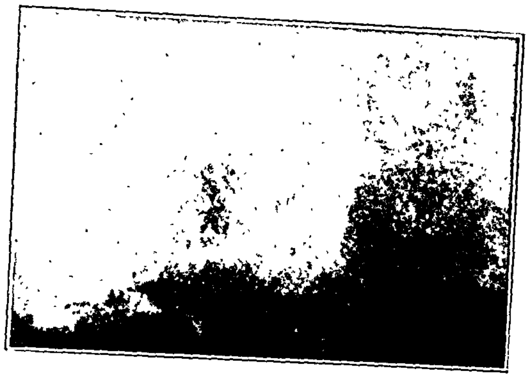

Fig. 16.—Multiple gall-stones.

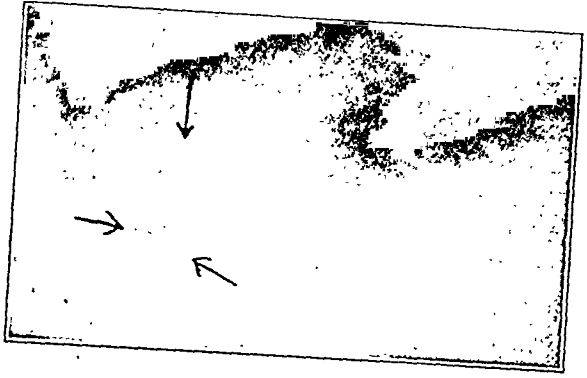

Fig. 17.—Multiple gall-stones.

6. In a number of cases I have observed a spastic manifestation in the stomach, sometimes a spastic indrawing on the greater curvature high up near the cardia and at other times a complete spasm of the pylorus as an associated sign of gall-bladder disease. The same sign has also been seen in duodenal ulcer, tabes, hysteria, appendix disease and even in hyperthyroidism.

7. In a few cases, very abnormal disposition of the sigmoid flexure of the colon has led to a diagnosis of gall-bladder disease. The roentgenographic demonstration of aberrancies of the sigmoid colon has been discussed by Pfahler, myself, and various others. The sigmoid may be procolic or retrocolic. In one remarkable instance, the aberrant retrocecal loop measured 54 inches from the iliopelvic junction to the rectum and was adherent every inch of the way, including adhesions to the duodenum and the stone-filled gall-bladder.

ABSTRACT OF DISCUSSION

Dr. Lewis Gregory Cole, New York: It is generally believed by the roentgenologist as well as by the profession at large that gall-stones do not show in the roentgenogram. The reason for this, I think, is largely, as Dr. Case stated, that we do not search for them as we should. I do not think that I could take exception to a single thing that Dr. Case said in his paper, except about the possibility of showing the sulci between the lobes of the liver. During the past six months I have found more gall-stones than kidney-stones, simply because I looked for them. They have to be differentiated. You cannot make a definite negative diagnosis, but you can make a definite positive diagnosis.

Dr. George Pfahler, Philadelphia: I believe that in 50 per cent. of these cases gall-stones can be demonstrated, and whether or not they throw a shadow depends on their composition. If they contain lime salts, they can be demonstrated. The kind Dr. Case showed were of that composition. In fact, gall-stones can practically all be demonstrated. Occasionally I can show a stone consisting almost entirely of pure cholesterin. A case of that kind was referred to me. The patient was passing blood in the urine and was extremely tender over the gall-bladder. In that case I found faint abnormal shadows near the common duct in two plates. I made a diagnosis of stone in the common duct and at the operation that diagnosis was confirmed. The stone was removed, and this shows that we can often go beyond the group to which Dr. Case referred. Such stones cannot be demonstrated by lantern-slides; but only by proper illumination and by one who is an expert in reading these negatives. They can also be demonstrated by a technic I described two years ago before the American Roentgen-Ray Society, namely, by bending the body strongly to the left. I wish to refer to a case in which such studies were most important to a patient suffering from severe pain in the right side for eight years. The appendix was removed, but the pains continued, and it was finally concluded that the pains were due simply to a desire to have morphin. A diagnosis of malingering was made. A careful study of the kidney showed no stone, but an examination of the gall-bladder region showed that the gall-bladder was filled with stones. Dr. Laplace removed 196 small, sharp-cornered stones. Every time one of these stones passed the patient had a severe colic. These are only a few examples of cases in which the practical application of this method will often keep us from making a faulty diagnosis.

Dr. A. D. Bevan, Chicago: I have followed this subject rather closely for a number of years. In 1898, when the early work was being done with the Roentgen ray to determine the position of kidney-stones, we did some experimental work to find what evidence we could obtain in cases of gall-stone disease. Our results were interesting. We took a series of stones, no matter of what composition, and put them in a large beef liver. Then we made a roentgenogram to find what stones gave a shadow and what stones did not. As has been very well stated here this afternoon, the presence or absence of a shadow depends entirely on the composition of the stone. We found that the pure cholesterin stones did not show any shadow at all. The stones that contained carbonated calcium gave a good shadow. Some stones did not cast as much shadow as normal salt solution. In looking over this evidence we must ask ourselves as practical surgeons of how much value this work is. I think it is of comparatively little value. The time has not arrived when the Roentgen ray is of any great value in making a diagnosis of gall-stone disease. The men who are doing a great deal of roentgenographic work encounter many cases in which they find this evidence. They are not surgeons, and therefore they come to the conclusion that this would be of value in a given number of cases. To the surgeon, on the other hand, who is operating on hundreds of cases of gall-stone disease, this means of diagnosis would not be of much value. I do not believe that it would be a help in more than one case in ten. I want to emphasize that point. In one case, for instance, the evidence was very confusing. The

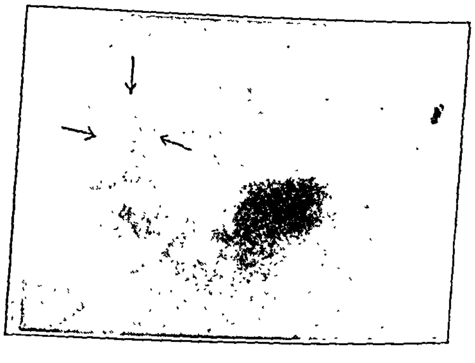

Fig. 18.—Multiple gall-stones.

clinical history was that of a typical common-duct case. The roentgenogram showed a definite stone in the position of the common duct. The operation showed that the stone was there. It was removed from the common duct. The conclusion was definite and absolute. You would hang a man on evidence of that kind. I placed that stone in some urine and found that it floated. It was a light stone. I took another picture of that patient and found the same shadow in the same place. It was a silent kidney-stone. I wish to emphasize the fact that the evidence given by the roentgenogram in determining the presence or absence of gall-stones is of very little value.

Dr. J. T. Case, Battle Creek, Mich.: In the part of the paper which I did not read I described Dr. Pfahler's technic to assist in the demonstration of gall-stones. Dr. Bevan's remarks are timely and should serve to repress youthful enthusiasm, but I should like to call your attention to a few facts. Among the last one thousand cases of bismuth-meal examinations made in my clinic for conditions such as gall-bladder disease, ulcer and carcinoma of the stomach, intestinal trouble, appendicitis and all kinds of abdominal conditions, I have demonstrated gall-stones in forty-eight. If only one-tenth of these cases can be diagnosed by the Roentgen ray, there were 480 cases of gall-stones among one thousand cases, and yet none of these cases were suspected clinically. I believe that the percentage—one in ten—is too high.

ROENTGENOGRAPHIC STUDY OF THE NORMAL KIDNEY, ITS PELVIS AND URETER*

SAMUEL B. CHILDS, M.D.
and
WILLIAM M. SPITZER, M.D.
DENVER

From our text-books on anatomy and from the dissecting-room we have learned the normal size, shape and position of the kidneys, and their pelves and ureters in the cadaver. When we try from roentgenograms to draw correct conclusions as to the size, position and contents of the pelves, calyces and ureters, or the difference in position of the kidneys and ureters in the prone and upright positions, we find such a diversity of opinion concerning the normal or abnormal conditions existing that we think it worth while to undertake the roentgenographic study of the normal kidney, its pelvis and ureter in the living subject. We hope thereby to fix a reliable standard for ourselves, so that deductions and diagnoses from our cases in this most important field may be found reliable and accurate, whether confirmed at operation or by the subsequent course of the case.

The normality of our cases was determined as follows: The history was carefully taken, and if anything was found to indicate previous or present kidney or ureteral lesions, the case was dropped. The clinical history being negative, the bladder urine was drawn and examined. If normal, the case was accepted for roentgenographic study. If abnormal, and we suspected that the condition was due to some abnormality in the lower urinary tract, the ureters were catheterized; if it was found that all the trouble existed below the lower ureteral orifices, the case was accepted and roentgenographic study of the kidneys and ureters undertaken. If any abnormal conditions were detected through this study, the case was thrown out of the series. Thus we did a great deal of work, and have but ten cases to report, with, of course, twenty normal kidneys. Previously we had formed certain ideas from the plates of a presumably normal kidney taken to show some pathologic condition of the opposite kidney. We have not included a study of these normal kidneys in this series because these cases could not meet the requirements demanded by us as to history, clinical findings, clean urine, etc.

The technic followed is here described: Roentgenographic catheters are passed into the ureters as far as possible. When they come to a stop in the kidney pelvis, collargol is injected by measured gravity pressure. We have used for this purpose an apparatus consisting of two 50 c.c. burets, ⅜ inch inside diameter, for the collargol, which is connected by rubber tubing of smaller diameter with a needle small enough to enter any size urethral catheter. This idea was adopted from Braasch's apparatus. We have added thereto an irrigating jar on the same stand for the purpose of supplying water for our cystoscopic examination. This apparatus is so raised that the bottoms of the burets are less than 2 feet above the level of the patient's body. We believe that this furnishes us with a comparatively slow flow of collargol into the kidney pelvis without much pressure. We do not cease injecting collargol into the pelvis until pain is positive on both sides, as we have found that the subsequent readings and interpretations of our plates are unsatisfactory if the pelves are not filled, and there is no way of determining this fact until pain is complained of. One of our cases, in which we stopped the flow of collargol before the appearance of pain, demonstrates that an interpretation of the plate is unsatisfactory when distention of the pelves has not been obtained.

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

On the appearance of pain, however, the flow of collargol is immediately stopped. From this point we have varied our technic, depending on whether we wanted to show the ureters, their shapes and angulations, or whether we desired to show where catheters go in normal pelves, either by partially withdrawing our catheters or by leaving them *in situ*. We have never, following this plan, used less than 4.5 or more than 15 c.c. in a pelvis. The percentages of collargol that we used varied from 8 to 20 c.c., depending on the stoutness of the patient, and we have found no more disturbance or pain with the high percentage than with the low, and have decided that pain, shock and subsequent temperature are caused chiefly by distention.

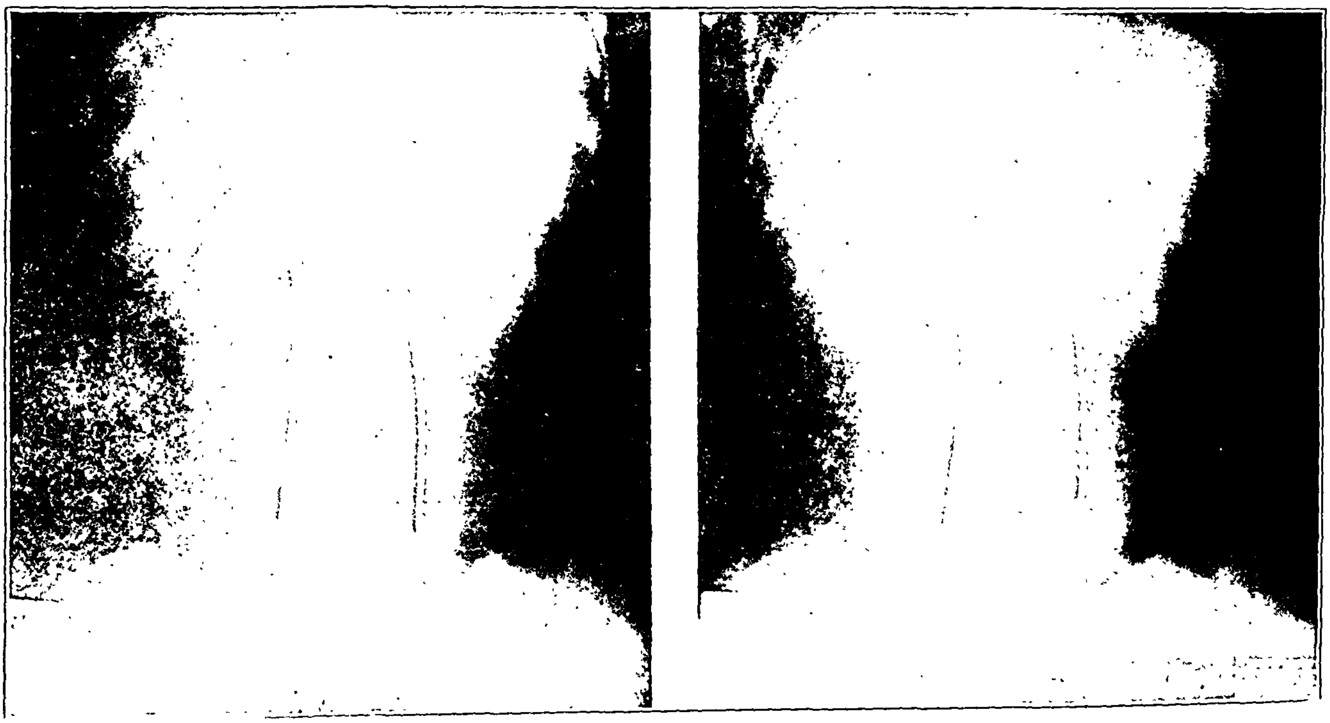

Fig. 4.—Series of normal kidneys. Miss R. B., Case 7. This may be cut out, pasted on a piece of cardboard, and the stereoscopic effect obtained with an ordinary parlor stereoscope.

The fact that injection should cease immediately on the appearance of pain is demonstrated by Case 9 in the accompanying table, in which, although we used no more pressure than for the others, we permitted the flow of collargol for a short time after the patient complained of pain, and the tubules on the plate resembled the branches of a delicate fern. This patient suffered with some pain, and had a temperature, varying from 99 to 101 for two weeks afterward, and the collargol was not completely swept out for about this length of time.

In the literature on this subject the report of a case appeared in which the collargol ruptured the parenchyma of the kidney, and appeared under the true capsule. One would infer either that there was undue pressure from a hand-syringe (whose pressure cannot be gauged) or an unduly long-continued flow under pressure. We wish to remark in passing that this work should be done only by men who are trained in it.

The stereoscopic plates are made with intensifying screens, the anode of the tube at least 26 inches from the plate. The tube is focused about the level of the third lumbar vertebra. Care has been exercised in our work to take all plates at the same point of respiration, that is, the breath held at the end of a deep inspiration. This is true of the plates taken in the recumbent and the standing postures. By this means we have been able to determine the mobility of the kidney over and above that produced by respiration. We have not tried to ascertain the amount of movement of the kidneys in respiration, and on the other hand, we have eliminated this feature from our series by the precautions just mentioned. A slight respiratory movement, while the plate is being taken, gives a hazy or double outline of the collargol-filled pelvis and ureter, and hence it is necessary that respiration cease entirely for the extremely short time required to take the plate.

The apparatus used was the Scheidel-Western transformer, first inductance tube drawing 35 to 40 milliamperes, exposure from three-fourths of a second to one and one-half seconds, depending on the weight of the patient.

We had found in our previous work that without stereoscopic plates we were unable to differentiate between kinks and curves of the ureters, and the course of the ureter was a matter of guess-work. We also found it difficult to know the relative position of calyces and of shadows connected with the kidney pelvis. With stereoscopic plates the relative position of the structures is apparent, and this is important.

We have found that generally we can show the kidney itself in the roentgenogram. It is obscured, of course, on occasions, by gas, but when this is not so it shows distinctly. We believe that it is of value to have the kidney itself appear on the plate because one can exclude a growth in or near this organ, judging from its size, shape and position, if it be clearly shown. We have failed to detect anything new in our study of the size and shape of the kidney. In the table it will be seen that the position of the normal kidney varies markedly. Some of these kidneys are to be found very high, and some very low. *One of the kidneys in Case 3*, although normal, is no doubt dystopic. The mobility, varying from nothing to 3.5 cm., as shown in the table, is determined by comparison between plates taken in the recumbent and the standing positions. After the patient was removed from the table and placed in a standing position he was asked to cough and make other forced respiratory efforts, and to raise his heels from the ground and come down forcibly. The change in position also intensified angulations of the ureters. Attention is called to the fact that in one case the kidney is actually in a slightly higher position when the patient is standing than when lying down, owing possibly to a change of focal point.

In our series we find that the capacity of the normal pelvis varies, as before stated, from 4.5 to 15 c.c., and we also find that the apparent size on the plate occasionally seems incompatible with the real capacity. When there is a single pelvis it seems to be always of the same shape, that is, convex on its upper border, concave on its lower, and points toward the spinal column, its axis being either horizontal or slanting slightly downward and forward to the ureteropelvic junction. The course of the ureter is never constant and the shape seems to be dependent on peristalsis to a great degree. Its extreme mobility and its loose connection with neighboring tissues are easily shown in the stereoscopic plates by the position it is forced into by the catheter, when the catheter is carried to the end of a calyx and meets with slight resistance.

Its length has been estimated as follows: At the time of examination, the distance that the roentgenographic catheter passes into the ureter is noted, and on the plate the distance from the ureteropelvic junction to the terminal end of the catheter is computed and subtracted from the total number of centimeters that the catheter passed out of sight into the ureter, thereby giving the approximately true length of the ureter. The distance the catheter disappeared into the ureter, heretofore, has been considered the ureteral length. It must be apparent, from our plates, however, that this is inexact, as variable amounts of catheter may be contained in the pelvis itself. The ureteral length is of importance, as by this means a dystopic kidney may be proved, in conjunction with roentgenographic work. If the ureteral catheter disappeared but 15 or 20 cm. into the ureter and was then brought to a halt, this would be of no value without the accompanying plates to demonstrate that the catheter was not brought to a halt somewhere in the course of the ureter by a stricture or bend, instead of being in the pelvis. For many other reasons it is well to know the ureteral length. This is but one of the many places in which it is shown that the urologist must always work with the roentgenologist to draw conclusions in these cases. We are convinced and feel with the rest of the urologic world that diagnoses are difficult enough to make under proper conditions, even with all the aid at our command, and are satisfied that as the worker employs more and more means and methods to draw his conclusions, his deductions, in proportion, will be more exact.

We have encountered but two main types of pelves, the single and the double pelvis as described by others. In Case 9 there are double pelves on both sides, in all the rest of the cases in this series there being single pelves. We find, if it be of any importance—although we cannot conceive why it should be—that the number of calices majores shown on the plates varies from three to six. Another observation, and one which we think is of value, is that the catheter, as a rule, in the normal kidney follows the superior or convex wall of the pelvis. This is due to the fact that the catheter has a tendency to travel in a straight line, is deflected by this wall and continues in contact with it until it enters a calyx. For the same reason, but not so frequently, the catheter travels into the superior oblique calyx, if we might so name it; or if there be no superior oblique calyx, it travels into the superior calyx. If the kidney pelvis were large and the calyces wide, no doubt the catheter would take a different direction and coil up in the pelvis or pass to a lower calyx, as we have occasionally seen.

Anatomists have described the kidney pelvis as a dilated portion of the ureter and have also described other dilatations and constrictions below the pelvis. They also inform us that the angulations exist in the ureter, normally, and tell us that the ureter is further constricted by structures outside of it, such as the spermatic artery, which crosses the ureter about the middle of its course; but we do not know, from observations made by others, how these normal kinks, constrictions and dilatations should appear in roentgenograms, and because of frequent peristalsis in the ureter we are not prepared to say whether all these constrictions actually exist or are caused by peristalsis; but we have repeatedly demonstrated that kinks, angulations and constrictions are common in normal cases. We believe that we have overcome the peristalsis of the kidney pelvis, a muscular structure, by maintaining the pressure of collargol while the plate is being taken. We accomplished this by having the end of the catheter still connected with the needle and tube which furnished the collargol, although the flow was shut off with a stop-cock. While no more collargol could flow in, in the majority of our cases none flowed out, as verified by cystoscopy. In measuring the capacity of the kidney pelvis, one must take into consideration that frequently quite a quantity of collargol flows into the ureter without appearing in the bladder, as in Case 10, and that this is generally estimated in the pelvic contents. We have found this filling of the ureters occurs most frequently in women who have borne children, and whose ureters appears to be large and lax. This condition can only be determined on the inspection of the roentgenogram.

Lastly, we come to the question of whether or not pyelography is justifiable, in view of its alleged seriousness. We are decidedly of the opinion that it is, because differential diagnosis between abdominal conditions and kidney and ureteral conditions have been made possible by this means, whereas heretofore medicine and surgery were held back because of the inability of the surgeon to differentiate between abdominal and pelvic conditions on the one hand, and kidney and ureteral conditions on the other. Despite the fact that we have had pain, shock or high temperature, or any combination of these, follow our investigations, all in moderation and all transitory, we feel sure that we have done no permanent injury either in this series or in any of our pathologic cases.

We would suggest that immediately following the work a hypodermic of morphin and a large quantity of water with some whisky be given the patients, the first of which will completely control the pain, and the latter produce a polyuria for the purpose of washing out the collargol which remains in the pelvis. We see no use in attempting to syphon the collargol from the kidney pelvis by leaving the catheter *in situ*, as we feel sure that the sooner the catheters are withdrawn the sooner will there be room for the fluid to leave the pelvis.

CONCLUSIONS

1. Pyelography is not only justifiable, but is necessary; however none but the trained urologist should attempt it.

2. Unless the lower border of the pelvis is concave, we consider it abnormal.

3. A pelvic content of over 15 c.c. should be viewed with suspicion and investigated further before its normality is accepted.

4. Movement of the kidney of from 1 to 3.5 cm. over and above the physiologic (respiratory) movement is normal.

5. The ureteral catheter, as a rule, enters the upper oblique calix and follows the roof of the kidney pelvis to do so, in a normal case.

6. Angulations, curves and kinks of the ureter are found in normal persons.

7. Stereoscopic plates are not only necessary, but imperative, to demonstrate intrapelvic and extrapelvic conditions, and the course and kinks of the ureter.

8. Length of ureter can be calculated only from the plate, and is of importance.

9. Pain, shock and subsequent temperature are caused by rapid distention of the kidney pelvis rather than by any particular drug or percentage of drug that is used, and are unavoidable, if one properly fills the pelvis for diagnosis, although none of these disagreeable sequelae need be produced to an extreme degree or cause much disturbance, and can be obviated to a great degree.

10. As the shape of the ureter is due to its laxity or tenseness, either of which conditions may be normal, and its caliber varies considerably in normal subjects, and as it is still further altered by peristalsis, care should be exercised in drawing conclusions that pathologic conditions exist because of apparent abnormalities of shape and course, or because of curves, kinks and angulations, or apparent constrictions.

ABSTRACT OF DISCUSSION

Dr. O. S. Fowler, Denver: I have found that it is not necessary to produce pain in order to get a satisfactory roentgenogram. Furthermore, I think it extremely inadvisable to inject enough to produce pain, for the reason that one may inject the kidney tubules, or go even farther than that. A few cases have been reported in which the kidney substance was ruptured with the production of an infarct. Therefore, I feel that it is extremely undesirable to produce pain, and I try to obviate it as far as possible. I consider it unimportant to determine the length of the ureter; in fact, you cannot determine the length by the insertion of the catheter. The catheter may meet an obstruction at 20 or 30 cm. or even farther, if you pass it up into a hydronephrotic pelvis. You cannot determine anything of value, therefore, by the distance you have inserted the catheter. If you meet an obstruction you had better stop there.

We would naturally expect the catheter to follow the upper surface, because that is the concave surface, and we would naturally expect it to follow the upper wall and to go into the upper calices. If you get it into the upper calyx and then keep pushing it in, it ought to curl up in the kidney pelvis.

The ureteral catheter smooths out all the angulations of the ureter when the patient is lying down. We do not have much trouble with the kidneys in patients when lying down. We want to see what these kidneys look like under normal conditions—fluid conditions—of the urinary tract. That is what the patient has to deal with every day of his life, and what is the object of putting in the catheter and trying to show something when the patient has the catheter in there! What we want to know is, is there any difficulty there under fluid conditions of the urinary tract? There may be anatomic deviations from a straight ureter. They may appear roentgenographically as though there were a kink. There are degrees of angulation and curving in these cases, and unless an angulation or curve is giving trouble, I say let it alone. It might give trouble in the future. I consider a kidney normal that is not producing symptoms, or if an obstruction cannot be demonstrated to which those symptoms can be referred. If you can demonstrate some other lesion to which these symptoms can be referred and cannot demonstrate something in the pelvis or ureter, then you should exclude the ureter.

Dr. W. F. Braasch, Rochester, Minn.: I do not think that it is necessary to cause any pain in order to make a good pyelogram. The pelvis is best injected by the gravity method, that is, by raising the silver solution above the level of the patient. Pain is not necessarily caused in that way, even though the pelvis is completely filled. Pyelography has been

§ Perhaps 12; not accurate; had to be estimated.

severely criticized for being the cause of severe pain, most of which could have been *obviated if the proper technic* had been employed.

Dr. W. M. Spitzer, Denver, Colo.: I have used in these cases, as in all our pathologic cases, the gravity method. When I spoke of causing pain, I did not mean excessive pain or pain which lasts a long time; but we do cause pain, and we do not stop until we get to the point of pain. We use an apparatus such as Dr. Braasch uses, a 50 c.c. buret, raised two feet above the level of the patient. You will cause pain if you use a needle of fair-sized caliber and a good-sized catheter, whereas you will not cause pain with a small-sized needle, the difference being not so much in the amount of the solution used, as in the rapidity with which it is injected. When you have distention of the pelvis, whether it is caused by a stone blocking the ureter and thus damming back the urine, or by a fluid injected, you are going to cause some pain, and you cannot avoid it.

In answer to the remarks made by Dr. Fowler: I was not discussing the pathologic kidney. I was simply showing the normal kidney. We took great pains to assure ourselves that these kidneys were as normal as we can prove them to be at the present time. If the urine showed that the least thing was wrong with it, we threw the case out of our series. We took great pains in other ways to prove our cases normal. I do not think an exhibition of pathologic kidneys shows whether my cases were normal or not or concerns this work in any way. The object of the work was to attempt to show the normal. If other people will help to demonstrate the normal, we shall have, after a while, a basis from which to deduce the pathology. Simply to say, "Here is a case that is pathologic because I say so," seems to me foolish, and that is the reason that we have done this work. We have demonstrated kinks in 60 per cent. of the cases in which we sought them in this normal series.

To read something from a plate, I think we must have a kidney pelvis well dilated with collargol. I removed a kidney for a very evident tuberculosis. It had to be torn loose from everything around it. The case was diagnosed as a hydronephrosis and the patient was operated on because there was a kink in the ureter, which demonstrates that some of us cannot read the pathology shown in our pyelographs and justifies the study of the normal, as a basis for our deductions as to what is, and what is not, pathologic.

THE EXTERNAL BONE CLAMP VERSUS THE INTERNAL BONE PLATE IN THE OPERATIVE TREATMENT OF FRACTURES *

LEONARD FREEMAN, M.D.
DENVER

So much has been said recently about Lane's internal bone plates that there is danger of losing sight of the advantages of the external bone clamp. Hence a brief comparison of the two should be of interest.

In operating on fractures it is often necessary to employ some artificial means for holding the fragments in position. According to circumstances this may be done with chromic catgut, wire, bone or ivory ferrules or medullary plugs, autogenous or foreign bone grafts, staples, internal bone plates, or external clamps of various patterns.

The ideal method would consist in the use of something which, while holding the bones firmly and not irritating the tissues, would rapidly undergo absorption, thus leaving no foreign body to cause delayed union and late infection. It should also be easy of application, with the least traumatism, and should not interfere with the process of repair.

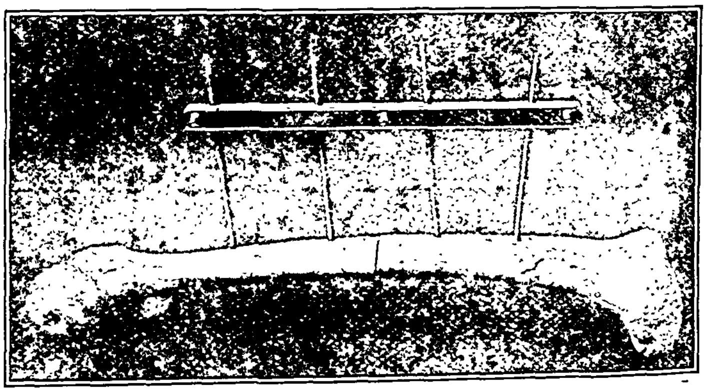
Unfortunately none of the procedures in use fulfil all of these requirements, although most of them answer sufficiently well in appropriate cases. At present the plate and the clamp are most in favor, although, in ununited fractures at least, the autogenous bone graft is rapidly gaining ground and may soon supplant both of them.

Great similarity exists between the internal plate and the external clamp. Both are fastened to the bone with the same number of screws, the only difference being that in one the part which unites them is outside the skin, while in the other it is beneath it. In fact, the clamp might be termed an external plate or the plate an internal clamp.

All external clamps have in common several screws, long enough to project well beyond the skin when they are inserted into the bone. The many varieties differ only in the mechanism by which the screws are held together.[1]

The advantages of the external clamp over the internal plate, in appropriate cases, are:

1. It can often be more easily applied, with less manipulation of the tissues and denudation of the bone. Holes can be drilled and the screws inserted with the fragments in almost any position. They can then be adjusted without the use of elaborate holding-apparatus and the screws instantly clamped (see illustration).



External bone clamp.

2. Nothing comes in contact with the line of fracture, as does an internal plate; and the screws themselves may be placed as far away from the break as may seem desirable—even in sound, uninjured tissues. This is of much importance, because, as is well known, the presence of a foreign body favors delayed or non-union, to say nothing of infection. In this connection Martin[2] says, "As a rule, the presence of a plate, instead of stimulating osteogenesis between the broken bone-ends, retards it." The possibility of placing the screws at a distance from the fracture is also of manifest advantage in cases in which the bone is comminuted.

3. In most instances an external clamp will immobilize the bone fragments even more firmly than an internal plate will, as may easily be demonstrated. This is because the long screws get a particularly firm grasp within the bone and the heavy external clamp holds them together with absolute security. The screws, if rigid enough, may be long without detriment, because they will be removed later; and the clamp may be heavy because it lies without the tissues. When a clamp is

---

* Read in the Section on Surgery of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

[1] The external bone-clamp was introduced into this country and popularized by Clayton Parkhill of Denver.

[2] Martin: Surg., Gynec. and Obst., September, 1912.

properly inserted, say in a fracture of the tibia or of the femur, the limb may be picked up by the foot and thrown about in any direction without fear of disturbing the fracture; but if a plate is employed this can seldom be done without danger of bending or breaking it, or of pulling the screws from the bone.

4. The principal advantage of the external clamp, however, is that it may easily be removed at any time without the use of a general or even a local anesthetic, thus avoiding a much-dreaded secondary operation and also the necessity of leaving a foreign body in the tissues with all the disagreeable possibilities that this implies.

Every one knows that while plates are being inserted all over the country, they are constantly being taken out, either by those who put them in or by others. If this were all it would not be so bad; but, in addition, sepsis is not infrequent, sometimes resulting in loss of limb, as I have seen, or even in loss of life. In our Denver hospitals, which, I venture to say, compare favorably with most others, many plates have been inserted, the majority of which have had to be removed for various reasons, and some of the results have been disastrous in the extreme.

Let us now consider some of the disadvantages urged against the use of the external clamp:

1. Its size and weight. This objection is easily disposed of. The large and heavy portion, which insures security and strength, lies outside, where it is productive of neither inconvenience nor danger of any kind—a large instrument being tolerated by the patient as easily as a small one. The screws alone penetrate the tissues, and they are often of no greater diameter than those of an internal plate.

2. The most plausible objection to the external clamp is the supposed great danger of primary or secondary infection. This has been frequently and strongly urged, but, I am convinced, without adequate reason. The situation may be put in a few words: If the operation is a clean one primary infection will not occur with clamp or plate. If the operation is not clean, infection may take place with either; but its effects will be less severe with the clamp, because of drainage afforded by the external screw-holes. And on the side of the clamp lies also the great advantage that it may easily be removed at any time without a second operation.

If secondary infection occurs with the external clamp, it is late in appearing, trivial in amount and confined strictly to the screw holes, as has been amply proved by the experiences of Parkhill, Lambotte, myself and many others. In fact such localized, non-spreading, secondary infection may be compared to that which is seen around sutures of silkworm-gut, although infection is more likely to take place in connection with sutures than with screws, on account of constriction of the tissues by the former.

Infection does not easily spread with either screws or sutures because a granulating channel is soon formed which affords a protecting wall against bacterial invasion. In order to elucidate this point more clearly some experiments were conducted on dogs by my associate, Dr. O. S. Fowler. By inserting screws through the soft parts into the bones he was able to demonstrate that the holes become lined with granulations in the course of three or four days (the specimens were examined by Dr. Philip Hilkowitz) and it is not unlikely that a certain degree of protection begins even earlier. Secondary infection, however, really does not occur until much later than this, if proper precautions have been taken, thus giving ample time for the walling-off process to become complete. On occasion I have left clamps in place for from two to four weeks without manifest infection, and others have had similar experiences. During this period considerable protection is undoubtedly afforded by loose dressings, which favor rapid drying of the secretions, and by the occasional application of alcohol or of weak tincture of iodin to the vicinity of the screw-holes.

3. It is said that external clamps are difficult to use in certain cases. This is undoubtedly true, especially near the ends of the long bones, where the terminal fragment is too small or the cancellous tissue too soft for the screws to obtain a sufficient hold.

The whole question may, I think, be fairly epitomized as follows:

Both the plate and the clamp have their legitimate uses. In the hands of surgeons especially skilled and experienced in work of this kind, like Mr. Lane, for instance, plates may be more or less successfully employed at will. With the great majority of surgeons, however, the external clamp, when practicable, should be the instrument of choice, although there will always be those who will prefer the plate, in order to demonstrate their ability to use it.

The external clamp is especially indicated in connection with the shafts of the long bones, when the fracture is not too near the epiphysis or too deeply situated, as in the thighs of extremely fleshy or muscular individuals.

It almost goes without saying that clamps should always be employed in preference to plates in compound fractures where there is danger of infection resulting from the injury. It being a foregone conclusion that whatever is put in will have to come out again, it seems purposeless to use something which cannot be removed without a special operation and which adds to the danger of sepsis by its proximity to the line of fracture and by its size.

Metropolitan Building.

ABSTRACT OF DISCUSSION

DR. JOHN B. MURPHY, Chicago: The subject of treatment of fractures is, at this particular time, paramount in our surgical clinics. The proposition of doing an open operation for a fracture is much more serious than is the proposition of opening the abdomen, because you are dealing with tissues which while not so dangerous to life if infection does occur are enormously more easily infected. If a man can do an open operation for fracture and obtain aseptic healing, with regularity, he is doing the ideal thing. The control of the possibility of infection, however, is not always in his hands. There are many conditions that contribute to the occurrence of infection in the reduction of the fracture and its permanent fixation, and I am pleased to know that the doctor is endeavoring to get an accurate and perfect apposition by means of a device that does not expose the line of internal laceration and the fracture to infection. The Lane plate is the ideal means, to my mind, of holding together mechanically the fragments of the bone, provided it is placed by a man who is a master of the technic and who always attains perfect asepsis. There is still another element, however, in the management of fractures that is being overlooked. Why is it that we are having ten, fifty, one hundred cases of non-union of fractures to-day, where we had only one in the decade from 1885 to 1895. My interpretation of that is that in the modern management of fractures with, first, the plaster cast; second, the Lane plate and, third, the instruments and appliances that absolutely immobilize the line of fracture there is not sufficient irritation to stimulate osteogenesis at the line of fracture. We have failed to learn what the Germans learned when they began to use plaster casts. The German surgeon, after applying the cast, starts his patient as an ambulatory case. He moves around and there is sufficient stimulation of the ends of the fragments to favor osteogenesis and healing of the fracture. The American surgeon, as a rule, puts on a plaster cast and confines the patient to bed for from five weeks to five months, and at the end of that time he is surprised to find not even the slightest effort at regeneration of the bones. Mr. Lane during his last visit in this country emphasized the fact time and again that the Lane bone plate should not be used in cases of non-union. He recognizes the fact that there is something in connection with the fixation of the fragments that retards or at least does not stimulate osteogenesis in non-union cases. Another point which I was glad to have Dr. Freeman mention, because it is a most important one, is putting foreign bodies into compound fractures. If we could only learn to keep our hands, our nails, our screws, our spikes and our bone-splints out of fractures that are in all probability already mildly infected, we would have much better results in the treatment of compound fractures. After swabbing the surface with iodin solution, a dressing of gauze soaked in alcohol should be applied and the whole limb immobilized for many days unless the temperature or other conditions indicate a change.

Dr. L. L. McArthur, Chicago: Heartily in favor as I am of the recommendations of Dr. Freeman, I want to emphasize the fact that the statement is not correct that a limb cannot be handled after the use of a plate, whereas it may be handled after the use of the apparatus he described. Having just returned from the Canal Zone, where the opportunities for the treatment of fractures have been surrounded by more difficulties than in any other portion of the world, I want to say that they have found there that the introduction of the Lane plate makes it possible for them to treat the terrible cases of fracture they have had. These fractures are the result of dynamite explosions and crushings; they are usually compound, and these Lane plates have been put on every one of them. I saw 210 roentgenograms of cases that had been plated, and every one showed that a plate can be used in these fractures with good results, and in such a climate as that the plaster-of-Paris cast cannot be used because it becomes limp in a week. Therefore we must not conclude that the bone plate applied in a dirty wound will not enable us to handle the limb like a simple laceration of soft tissues. It can be done.

Dr. A. E. Hertzler, Kansas City, Mo.: I wish merely to throw out a few points as to why non-union occurs when a Lane plate or any other metallic appliance is used. The first step in wound healing is the precipitation of fibrin in the exudate, and anything that prevents that from occurring, prevents healing of the fracture. That is the whole problem. When a piece of metal is placed in a tissue a large amount of exudate is formed which does not coagulate readily or may remain permanently in a fluid state. Different metals act in slightly different ways. Silver produces more of an exudate than any other metal I have tested. Aluminum bronze produces the least. The problem in using a plate is to prevent the collection of this exudate. The best means for doing this is to provide drainage, so that the fluid can escape, or to place the plate in a tissue the least likely to produce exudate. For instance, in the thigh, in which there are large pads of muscles, more of this fluid collects than in the leg. For the same reason less fluid collects on the anterior surface of the tibia than on the external surface. Therefore the plate should be placed in the subcutaneous connective tissue rather than in the muscle bed when this can be done. If we are forced to use a splint where there is much muscle tissue, with the attendant abundant exudate, non-union will occur less often if the excess of exudate is drained away from about the plate until the ends of the bones not in touch with the splint have had time to become imbedded in fibrin—about forty-eight hours.

Dr. Carroll W. Allen, New Orleans: Dr. Parham has a method which is particularly applicable in the treatment of spiral or comminuted fractures with which it is not necessary to place a clamp on by screws or to use a nail through an oblique fracture. The instrument consists of two parts: (1) a metal band one-fourth of an inch in width with one end expanded and containing a slit through which the other end is slipped, making a loop; and (2) an apparatus consisting of a screw-rod, working on the principle of an écraseur, between two parallel steel bars for the purpose of drawing up the band and tightening it. In applying the band this is first placed around the bone at the site of the fracture with the oblique fragments adjusted, and one end is slipped through the slit at the other end and then attached to a hook on the screw-rod in part two. The screw is then worked, drawing up and tightening the band around the bone. When it is sufficiently tight the instrument is bent over causing the band to be bent on itself and clinching it. The band is then cut off close with a pair of pliers and the instrument removed.

Dr. Leonard Freeman, Denver: You will remember that my plea was not for the universal use of the clamp in preference to the plate, but merely for its more frequent use in suitable cases. Dr. McArthur has made me say that a fractured limb could be picked up by the heel when a clamp was used, but not where a plate was employed. What I really said was that the limb could be picked up just as well when the external clamp is applied, as when the internal plate was used, and perhaps better. He said that in Panama many metal plates were put in. It would be more interesting to know not the number of plates put in, but the number of plates that have had to be taken out afterward. The number is probably considerable. Dr. Hertzler spoke of the reasons for non-union and insisted that drainage would be desirable. This is obtained with the external clamp. One of the main reasons for non-union when the internal plate is employed is that the metal comes in contact with the line of fracture. With the external clamp there is no metal in contact with the line of fracture, or, of necessity, anywhere near it.

A STUDY OF THE USE OF ICE AND OTHER MEANS OF PRESERVING FOOD IN HOMES*

JOHN R. WILLIAMS, M.D.

ROCHESTER, N. Y.

The problem of pure milk is only partly solved with the introduction of clean milk into the home. The cleanest and purest milk may soon become foul if adequate means for its preservation are not used. It is well known that bacteria multiply with great rapidity above 50 F., while below that temperature their growth is held markedly in check. These facts are of importance to mothers and housekeepers, also to milk commissions and dealers, because charges of "bad milk" are often unjustly made against those interested in pure-milk work.

In a recent study of the market milk problem in Rochester, it was noted that for purposes of economy nearly half of the families of the city endeavor to get along without ice. In such homes condensed milk, proprietary milk and dipped milk purchased at the near-by store are mainly used. These facts led me to investigate more intimately the use of ice in homes and the means available for the preservation of food. Five sections of the city, representing socially and economically different classes of people, were studied. Upward of a hundred homes in each district were visited. Information was secured, when possible, along the following lines:

1. Inquiry into the use of milk, means of caring for it, etc.
2. Temperature measurements of refrigerators, living rooms and cellars.
3. The make, size and description of refrigerator.

---

* Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

4. The amount of ice used weekly and yearly, the cost of the ice, name of dealer, etc.

During the warm months of the year, milk is delivered during the night or early morning, on an average of three hours before the family is awake. When no box is provided for receiving it, it must be deposited on the door-step where it is exposed to the heat, dust and the attentions of the domestic animals of the neighborhood. Few homes in those sections occupied by working people are equipped with boxes for receiving milk. In an investigation on this point, of 604 homes examined, only eleven had milk boxes. Houses in the well-to-do sections are better equipped, for 359 out of 411 had proper facilities for receiving milk. The exposure of milk to warm air for three hours or more is sufficient to raise its temperature at least 10 degrees.

The usual means of preserving perishable fresh foods in the home is to store them in a cool place as the pantry, cellar or refrigerator. When the latter is not afforded, either the cellar or living-room is used. In a former and more extended inquiry into the use of ice in all parts of the city, it was learned that 2,243 homes of 5,431 examined did not use ice. In the present and more limited investigation, in which the very rich and very poor were largely avoided, 161 homes of 519 studied were not using ice any of the time. It is probably within the truth to say that half of the homes in the city rely the entire year on the cellar or pantry for their food preservation, and that more than three quarters of the homes deny themselves the use of ice, excepting for a few weeks during midsummer.

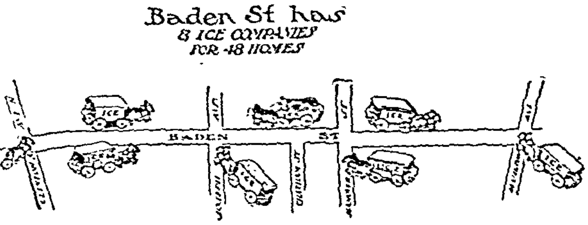


Fig. 1.—The wasteful method of ice distribution. There is a different ice dealer for each five to fifteen consumers on every street.

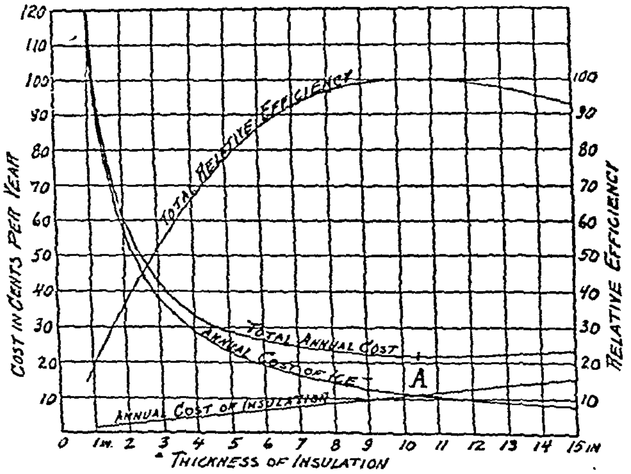

Fig. 2.—Chart (Lundgard) showing the relation of thickness of refrigerator wall made of the best insulation to the efficiency of the refrigerator, and also the comparative cost for operation per square foot of wall surface.

In view of these facts temperature observations of cellars and living-rooms where food is stored, as well as refrigerators, are of importance. In Table 2 it will be seen that not one living-room was found having a temperature below 60 F., nor was one cellar discovered having a temperature below 55 F. It is clearly evident therefore that these rooms during the warm months of the year, at least, are not sufficiently cold to protect food from bacterial decomposition.

In the study of ice-boxes, 243 were examined. Of these only 103 had a temperature below 50 F. The other 143 registered above that temperature and were therefore worthless for preserving food. As would be expected, a better class of refrigerators is to be found in the homes of the well-to-do; nevertheless, 45 per cent. of these had temperatures above 50 F., while nearly 70 per cent. of those found in the homes of the working people exceeded that temperature.

TABLE 1.—USE OF ICE AND MILK AND THE NUMBER OF DEALERS ENGAGED IN THEIR DISTRIBUTION*

Section	No. Homes Studied	No. People in Homes	No. Homes Taking Ice	No. Ice Companies Supplying Section	No. Milk Dealers Supplying Section	No. Homes Having Milk Boxes

Italian laboring	54	199	4	..	..	2
Totals	519	2,316	358	..	..	124

* The foregoing data do not fully show the waste in ice distribution occasioned by the overlapping of routes. There is a different ice company on every street for each five to fifteen consumers. In the first sction, on Dartmouth Street there is a different distributor for each eight consumers. In the Jewish section, on Baden Street eight ice dealers supply forty-eight homes. In the American laboring section on Adams Street there is an ice dealer for each four consumers.

SUMMARY

Refrigerators studied	243
Refrigerator temperatures below 50 F.	103
Refrigerator temperatures above 50 F.	140
Refrigerators in well-to-do section below 50 F.	61
Refrigerators in well-to-do section above 50 F.	49
Refrigerators in laboring section below 50 F.	43
Refrigerators in laboring section above 50 F.	91
Number of cellars or living-rooms below 55 F.	0
Number of living-rooms examined	228
Number of cellars examined	253

The main reason for the inefficiency of these refrigerators is to be found in their defective construction and insufficient insulation. Most of them are wooden boxes built of half-inch lumber, and are lined with galvanized iron or zinc. The walls vary in thickness from less than 2 inches to less than 4 inches (see Table 3). The space between the metal lining and the wooden sides usually contains insulating material, as paper, felt or mineral wool. In many of them nothing more is to be found than a sheet or two of paper. Since the efficiency of a refrigerator depends in large part on the character and thickness of the insulating material, consideration must be given to these factors. It has been proved both experimentally and practically that confined air or a partial vacuum are the best insulators. Indeed, it is the air entrapped within its cellular structure which retards the passage of heat through a material and gives it insulating value. The air must be confined, for circulating air is a good medium for the conduction of heat. A good insulator therefore must have a physical structure which will hold air within its cells or between its fibers. Moreover, it must be water-proof. Moisture, because of its greater power of heat conductivity, is a fatal enemy to perfect insulation.

Totals	35	114	49	24

* A *properly constructed* box, to be economically operated, should have a wall of efficient insulating material at least 6 inches thick. Such a box at the current price of ice will have a theoretical efficiency of about 80 per cent. The 149 refrigerators whose wall thickness is less than 2¼ *inches*, even were they made of the best possible construction, could not have an efficiency above 40 per cent. The remaining seventy-three refrigerators with walls averaging less than 3 inches could not have an efficiency above 50 per cent. As a matter of fact, with the shoddy and imperfect insulating materials used, most of the ice-boxes in *common* use rate far below their theoretical efficiency.

* This table shows, among other things, the seasonal character of the use of ice. This adds greatly to the cost of distribution, because it necessitates a large investment in equipment, most of which is idle during half the year.

A refrigerator wall which contains a space large enough to permit of air circulation will be found defective. Wood, felt, mineral wool, charcoal, sawdust, wood-ashes, etc., are fairly efficient when they are dry, but when damp or wet their efficiency markedly declines. When an efficient insulator is used there is very little difference between the temperature of the inside of the box and the temperature of that side of the metal lining which is next to the insulating material, consequently there will be very little deposition of moisture on the metal lining to be absorbed by the insulator. When the insulator is inefficient, however, the temperature difference is considerable and there is marked condensation of moisture on both sides of the metal lining. If this moisture is absorbed by the insulator it materially lessens its efficiency. In any event it causes the metal lining to corrode and makes the box damp and insanitary. Most of the commonly used insulators take up moisture with avidity, and for this reason most of the cheap refrigerators in common use will be found coated on the inner side of the inside wall with slime and the mineral salts resulting from the metallic corrosion.

Properly made cork board is probably the best-known and most efficient insulating agent. It is made of ground cork pressed into slabs and heated until the resins in the cork cement its particles together. It is to the remarkable physical structure of cork that its *insulating efficiency* is due. It consists of a woody material, filled with tiny air cells through which air circulation is not possible; moreover, it is impervious to moisture.

The comparative value of dry wood and the best cork board is as 1 is to 5; that is to say, 1 inch of cork board is equivalent in insulating value to 5 inches of wood. Since it requires 6 inches of cork board to give approximately 80 per cent. of efficiency in cooling, at the current prices of ice, it follows that few refrigerators in common use have an efficiency above 25 per cent. Indeed, the low-priced boxes used in the homes of working people are probably less than 15 per cent. efficient. This means that of 100 pounds of ice put into the refrigerator, at least 80 pounds are used in neutralizing the heat which percolates through the wall. It is worthy of note that the market is flooded with these shoddy ice-boxes. No less than seventy-five different makes were

* Two hundred and twelve families pay $10 or less per year; 109 families pay more than $10 per year. It is worthy of note *that at least 75 per cent.* of the money each family pays for ice is wasted, partly in the uneconomical method of distribution, but chiefly in the inefficiency of the refrigerators.

found among the 243 examined. Few of them bear the names of their makers, which suggests that the manufacturer is not proud of his handiwork.

The rate paid by the consumer for ice varies according to the amount used, the amount taken at each delivery, and the ability of the purchaser to pay for it in advance. Poor people living near the railway tracks get it at the cars for 20 cents per hundred pounds. If it is delivered to their homes they pay from 40 to 75 cents per hundred pounds.

The cost of harvesting and storing natural ice is so variable that it is difficult to determine it even approximately. It is probably within the truth to say that it costs less than $2 per ton. It costs between $2 and $2.25 per ton to make artificial distilled-water ice, although by some of the newer methods this cost has been materially reduced. The consumer pays the dealer the difference betwen $2,25, the cost of manufacture, and $8.50 per ton, or $6.25 for distribution. Thus the cost of distribution is nearly three times the cost of manufacture. One reason for this is the wasteful method employed. In Rochester a different ice company will be found supplying each five to fifteen consumers on every street, necessitating a tremendous waste in labor and delivery equipment.

CONCLUSIONS

The data gathered in this investigation warrant the following conclusions:

1. The temperatures of cellars or living-rooms in dwelling-houses are not sufficiently low during the warm months of the year to protect milk and other perishable foods from rapid bacterial decomposition. Therefore an efficient refrigerator in the home is a necessity.
2. Most of the refrigerators in common use are almost worthless and grossly uneconomical.
3. There is a large field for the manufacturer who will make a properly insulated and efficient box which can be sold at a moderate price.
4. If more economical methods of ice manufacture and distribution were employed, the cost of ice to the consumer could be materially lowered.
5. If to this saving were added that which would result from proper ice-box construction, refrigeration vastly superior to that now found in the average home could be had for at least one-fourth the present cost.

388 Monroe Avenue.

ABSTRACT OF DISCUSSION

Dr. L. S. B. Robinson, St. Paul: The preservation of the lives of babies among the poor often depends on the ability of the family to obtain ice, the cost of which is often prohibitive. The people of St. Paul are at present witnessing the formation of an ice trust, and in another year or two they expect to see the monopoly completed and the price increased. The Fabian Society has been holding meetings in St. Paul for the last three weeks to arouse public sentiment for a municipal ice plant. As president of the society, I have given the ice business in different parts of the country careful study and the cost as we have found it is even less than the figures Dr. Williams gives.

In a cold climate like ours natural ice is cheap. Men who have been in the business tell us that an ice-house on the shore of a lake can be filled for ten cents a ton; freight into the city is estimated at forty cents a ton. If ice is cut from a nearby lake and hauled at once to an ice-house in the city it has been put up there at a cost of fifty cents a ton. From 40 to 45 per cent. is allowed for shrinkage, so that nearly double the amount sold must be harvested. We are therefore safe in placing the cost at one dollar a ton.

Distribution is the expensive item. The testimony of men in the business and the books of those bought out last year show that they do not pay over $1.50 per ton for delivering ice into the ice-box. That makes a total of $2.50. The selling price is $7 a ton. We have demonstrated that the municipality could undertake the business at $4 a ton, pay the same wages for much shorter hours of labor and still have enough profit to pay all overhead charges and retire the bonds after one year on a harvest of a quarter of a million tons.

In Tucson, Ariz., the Santa Cruz (artificial) Ice Co. reports ten years' experience. On a charge of twenty-five cents per hundred pounds, or a rate of five dollars a ton, they have set aside 5 per cent. for depreciation and made 15 per cent. dividends on their investment, even in such a hot climate. That the municipality could deliver ice to the consumers for about half the present price is plain on careful study.

Dr. J. R. Williams, Rochester, N. Y.: I have been asked to describe a simple, model ice-box. An ice-box, such as I have in mind, may be made by anyone handy with tools or by a carpenter at a small cost for labor. It should be made of cork-board, which comes in slabs of any desired thickness and in convenient lengths and widths. A skeleton frame of wood should be made of the shape and capacity of the ice-box desired. On this frame should be tacked the cork-board slabs, which should first be coated with tar or asphaltum. One surface should be left for the door. After the first layer of slabs has been attached to the frame, a second layer should be applied, over the first, the two being cemented together with tar or asphaltum and the slabs toe-nailed to each other. Care should be taken to lap the joints in fastening on the slabs. The cork-board should be at least 2 inches thick. After the box has been made, the frame should be removed and the inside and outside of the box coated with a very hard-surface cement about one-fourth of an inch thick. A door may then be made of wood, with a cork-board lining. It should be beveled and fit as tightly as possible into the door-frame which should also be made of wood. A small box such as I have in mind may be made for about twelve dollars. It will have far greater efficiency and almost as much capacity as a forty dollar refrigerator.

How much one is justified in paying for a refrigerator depends largely on the cost of ice. If ice is to be had for small cost, one can afford to waste it in poor insulation, but if ice is expensive, and it is in most American cities, it will be found economical to provide good insulation, which means the purchase or making of a good refrigerator. A small, efficient, built-in refrigerator should be a part of the equipment of every small home, just as much as is the bath-tub or furnace.

The community should control the manufacture as well as the distribution of ice, to the end that it may be had freely and cheaply by all its citizens. By the most approved methods, artificial ice can be made for about $1.10 per ton. By the older methods, still commonly used, it costs about $2.10 per ton. The average cost of ice distribution, of all business, in several American cities, is about $3.25 per ton. The consumer now pays about $6 per ton for distribution.

Infant Mortality in Bavaria for 1912.—According to the tables of the Royal Statistical Institute, 37,006 children under one year died in 1912, exclusive of stillbirths. This is a diminution compared with the previous year of 9,659 or 20.7 per cent. Among these there were 30,855 legitimate and 6,151 illegitimate children. If the number of infant deaths in this year is compared with the births, the infant mortality in 1912 amounted to 17.7 per cent. and that for 1911 to 23.3 per cent. About a third of the infants born did not live through the first month and more than half failed to survive their first quarter. The statistics show that illegitimate children have a greater relative mortality, especially in the first months of life than children born in wedlock. The mortality is relatively slightly greater in the country. The summer months of 1912 do not show so high a death-rate as those of 1911, a difference due to the excessive heat of the summer of 1911. As is well known, the danger from the heat is best avoided by breast-feeding, careful handling of the milk supply for infants, not overloading infants with clothing, and care in cooling the living-rooms.

CLINICAL OBSERVATIONS ON ESSENTIAL HEMATURIA *

WILLIAM F. BRAASCH, M.D.
Attending Physician to the Mayo Clinic, St. Mary's Hospital
ROCHESTER, MINN.

For want of a more accurate term, I have retained that of "essential" for the type of hematuria which has not as yet been explained by any of the definitely established renal conditions causing hemorrhagic urine. The term "essential" should be limited to those cases of hematuria in which there is neither clinical evidence of renal insufficiency, visible organic change in the renal parenchyma nor any evidence of renal infection. The operative records of the Mayo clinic up to June 1, 1913, show twenty-six patients operated on for renal hematuria for which no evident cause could be found, and the clinical records show fifty-one patients not operated on in which the clinical diagnosis of essential hematuria was evident.

SYMPTOMATOLOGY

Sex.—Of the 77 patients, 58, or 75 per cent., were males and 19, or 25 per cent., females. The preponderance of males is noteworthy and is in keeping with that of renal infection occurring in the male.

Age.—At the time of examination 6 patients were under 30 years, 10 between 30 and 40, 24 between 40 and 50, 17 between 50 and 60, and 12 over 60. The majority of cases occurred in persons between the ages of 40 and 50, while only a small number of patients were below 30 years.

Localization.—On cystoscopic examination the disease was localized to the right side in 51 cases and to the left side in 26. Pain was described as a dull ache across the sacrum in 10 of the 77 cases, in either lateral abdomen in 6 cases, but never to such a degree as to be of any practical significance. It was described as severe in 5 cases, and then only with hematuria, the pain evidently being caused by blood-clots blocking the affected ureter.

Duration of Symptoms.—Of the 26 patients operated on, hematuria had first appeared over a year before in 16, or 61 per cent., over 5 years in 10 cases, or 38 per cent., and 15 years or more in 5 cases, or 19 per cent. It had continued prior to operation for a year or more in 5 cases, or 19 per cent., over 3 months in 18, or 69 per cent., and over a month in all but three of the cases. Of the 51 patients not operated on, hematuria was noted less than three months before in 23 cases, over a year before in 12, or 23 per cent., over 5 years in 10, or 19 per cent., and over 10 years ago in 5, or 9 per cent.

Physical Findings.—In three of the cases the affected kidneys appeared to be enlarged, on palpation, as though there might be tumor, but at operation they were found to be large, normal kidneys. In three other cases the kidney was described as low-lying and movable, in two of which the condition was found bilateral. Evidence of a central nervous lesion or marked neurosis was absent in all. In the 34 cases in which the blood-pressure was recorded the average was 132; in 2 cases it was more than 150. Ophthalmoscopic findings were practically negative in all. The general strength was lowered to such a degree that 19 of the 26 patients operated on were unable to carry on their daily occupation and only 6 of the 51 patients not operated on. The average hemoglobin estimate of the patients operated on was 63 per cent., while that of the patients not operated on was 84 per cent.

Urinalysis.—The specific gravity of twenty-four-hour specimens taken in 21 of the cases in which there was operation was below 1.015 in but 3 cases. In the other cases the average was 1.023. Albumin in varying amounts was found in all the cases in which operation was performed, as was to be expected as a result of the hematuria present at the time of examination. A few hyaline casts were found in 4 cases and occasional granular casts in 2 cases. A few microscopic pus cells were found in 5 of the cases in which the patients were not operated on.

Hematuria.—The hematuria was reported as being present in a marked degree in 54 cases, or 70 per cent., and but slightly in 23 cases, or 30 per cent. In 63 cases it varied in degree at various times.

Pyelogram.—The pyelogram with essential hematuria necessarily shows the outline of a normal pelvis. Evidence of abnormality would call our attention to the probability of some other condition being present even though no other symptoms were found.

DIFFERENTIAL DIAGNOSIS

The diagnosis of essential hematuria is most often confused with that of chronic nephritis, infectious nephritis, pyelitis, neoplasm, tuberculosis and lithiasis.

Chronic Nephritis.—The hematuria of nephritis is sharply defined from that of essential hematuria. It is usually present in a lesser degree and may vary from day to day. Scanty urine and the presence of many granular casts, edema, headache, increased arterial tension, lesions in the retina, any or all of which characterize nephritis, are necessarily absent with essential hematuria. Borderline cases which may have some characteristics of both conditions rarely occur. The conditions are usually widely separated clinically and it is difficult to understand from a clinical point of view how any relationship can be traced between the two conditions. When hematuria occurs with chronic nephritis, it is usually regarded as a terminal symptom, whereas it may be disregarded in a case of proved essential hematuria.

Infectious Nephritis.—Chronic infection in the kidney may be the cause of hematuria often resembling that of essential hematuria. It may appear insidiously without clinical evidence of infection other than microscopic pus and bacteria in the urine. More often, however, it is characterized by attacks of dull pain referred to one or both kidneys, chills and fever, together with microscopic pus, bacteria and gross hematuria. The hematuria is usually slight or comparatively moderate in degree. It may be present only during the acute attack or it may appear irregularly without the clinical evidence of infection. Pain, which is usually slight with essential hematuria, may be marked with the infectious nephritis, and is more often accompanied with fever and chills and other evidence of infection. The infecting organism can usually be identified in the urine taken under aseptic precautions. As Billings[1] has reported, the hematuria and other symptoms may disappear on administering autogenous vaccine. This was the result in one of four cases in which the vaccine was tried at the Mayo Clinic. The clinical evidence of renal insufficiency is usually absent until late in the disease. Although this condition is more often bilateral, four patients have been operated on in whom the clinical findings and subsequent course would indicate that the infection was unilateral. In these cases the kidney was found at operation to be smaller than normal, soft and irregular in contour. On section cicatricial changes of evident previous infection were apparent. Needless to say, with essential hematuria the urine should be free from pus and bacteria. The cicatricial changes in the pelvic outline of infectious nephritis as shown in the pyelogram are not usually extensive enough to be of diagnostic significance.

---

* Read in the Section on Genito-Urinary Diseases of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

[1] Billings: Am. Jour. Med. Sc., 1910, cxxxix, 625.

Bleeding Pyelitis.—Hematuria is occasionally present with chronic infection of the renal pelvis. It occurs with a chronic indolent infection confined largely to the pelvis and without much active destruction of the substance of the kidney. The infective process may involve the tissues about the renal pelvis and the adjacent ureter to a varying degree. Subsequent cicatricial contraction and adhesions will bind the pelvis and renal pedicle firmly and distort the pelvic lumen. When the upper ureter is involved it may either become dilated or partially constricted as a result of the cicatricial process. The mucosa of the pelvis in such cases shows irregular areas of inflammation and congestion which bleed on touching, and on close inspection appear to be granular. Between these areas the mucosa may be seen pale and glistening as the result of the chronic cicatricial changes. On microscopic examination the granular mucosa shows a papillomatous proliferation of cells. The latter condition was first described by H. Chiari[2] and recently by von Frisch,[3] and is called pyelitis granulosa. Occasionally the papillae alone are involved and the hematuria may result from the consequent papillitis. The hematuria which is seen occasionally with extensive hydronephrosis is caused by a similar condition in the mucosa, as the evident result of a chronic indolent infection. Clinically, hematuria of pyelitis may be subjectively differentiated from the essential hematuria by the character of the pain which frequently accompanies pyelitis. It is usually a dull, persistent pain with irregular acute exacerbations occurring without evident cause. Pain with essential hematuria is exceptional and occurs only as the result of an occluding blood-clot. Bleeding pyelitis might be confused with that of infectious nephritis, which, however, occurs more often in typical attacks with chills, fever and slight hematuria. On urinalysis microscopic pus will always be found present with pyelitis granulosa. Because of the indolent type of the infection but a few pus-cells may be present among the red blood-cells. Needless to say, only the specimen obtained by ureteral catheterization is of value, because pus-cells in the voided urine may come from any extrarenal source. The most accurate method of differential diagnosis is obtained through pyelography. The outline of the pelvis and adjacent ureter will appear irregularly narrowed and dilated. One or more of the calices may be irregularly dilated; more often they are effaced.

Neoplasm.—Although the hematuria of neoplasms is often present to a marked degree like that of essential hematuria, it usually persists but a short time and appears at irregular intervals. Unfortunately the occasional short hemorrhage does not cause the average patient to consult a physician so often as the protracted one. The presence of tumor will usually identify the nature of the hematuria, but in twelve of ninety-one patients operated on for malignant tumor of the kidney at the Mayo Clinic, definite tumor could not be determined clinically. It is this group of tumors which is easily confused with essential hematuria. Two methods are available in identifying the existence of a surgical condition, namely, pyelography and the renal functional estimate. It has been shown that the kidney with essential hematuria will not manifest any marked decrease in functional activity as measured by the secretion of phenolsulphonephthalein injected. It has been my experience that non-infected neoplasms without hematuria will show decrease in function in but 25 per cent. of cases. Unfortunately, renal tumors too small for definite palpation would show even a smaller percentage. Furthermore, profuse hemorrhage offers considerable technical difficulty in the accurate estimation of the amount of dye secreted. With marked comparative reduction of functional activity of the bleeding kidney, however, the existence of neoplasm should be suspected. Pyelography will more often be of value in ascertaining the existence of neoplasm by demonstrating an abnormal outline of the renal pelvis subsequent to tumor-retraction. While recognizable deformity of the pelvis may be demonstrated in over two-thirds of tumors of the kidney that come to operation, early tumor may not show recognizable deformity. Nevertheless, any tumor that is so far advanced as to cause hematuria will probably cause recognizable pelvic deformity. Even after all possible clinical evidence has been obtained, the question will often be raised whether or not operation is indicated. Tumor of the kidney was discovered at operation in two cases in which the clinical evidence rather suggested essential hematuria.

Renal Tuberculosis.—Occasionally the first and only evidence of renal tuberculosis is hematuria. In such cases the hematuria will usually be well marked and persist but a day or two, often showing but one hemorrhage. In the absence of pus in the urine and other evidence of tuberculosis on physical and cystoscopic examination, its existence could easily be overlooked. If there is any probability of tuberculosis, guinea-pig inoculation should always be made. Of three cases of hematuria regarded on clinical examination as being essential, two were proved to be tuberculous on subsequent examination, and in one the patient was reported as having died of renal and pulmonary tuberculosis.

Lithiasis.—A small stone pocketed at the end of a calix may be the cause of an otherwise symptomless hematuria and remain undiscovered even with the most careful roentgenographic technic. Urinalysis will usually show the presence of old blood-cells but no pus. A careful search should also be made for crystals, particularly those of calcium oxalate, which, if present in a considerable quantity, would be very suggestive of the existence of stone. On exploring in two cases regarded clinically as essential hematuria, such a stone was found at the end of a calix in one. In the other case a stone 2 cm. in diameter was found in the cortex, which, because of its soft character and the unusual obesity of the patient, did not show in the roentgenogram. Two more patients regarded clinically as having essential hematuria but not operated on reported having passed small stones several months after returning to their homes.

Renal Varix.—With the publication of a case showing angioma of the renal papilla, Fenwick[4] advanced a new explanation for a certain group of cases which had hitherto been called essential hematuria. It was at first believed that this condition would explain a large proportion of cases of essential hematuria. Recently a number of such cases have been reported in American literature. These might give the impression that the condition is a common one. Any report of such a condition without a microscopic section showing the dilated condition of the papillary blood-vessels cannot be of accurate value. Clamping the pedicle and consequent congestion of the tissue of the kidney may cause the papillae to appear so engorged as to give an impression of abnormality. True angioma is a comparatively rare condition and can explain but a very small percentage of bleeding kidneys. One such case has come under our observation in which microscopic section showed the typical dilated structure of the blood-vessels. The condition may be readily confused with the varicose condition of the blood-vessels adjacent to the pelvis as the result of insidious infection in the pelvis and surrounding tissues. With infection of the tissues the veins of the papillae will occasionally be found dilated on microscopic section. Leukoplakia of the pelvis was discovered on exploring the pelvis of the kidney in a case believed on clinical examination to be bleeding, because of essential hematuria. Pyelography will not as a rule be of much value in identifying the changes which affect the pelvic outline but moderately.

[4] Fenwick: Brit. Med. Jour., June 17, 1905.

After-Course.—Of the 26 patients operated on, nephrotomy was performed in 12 cases and neprectomy in 16. Exploration was made in 1 case. In 2 of the 12 patients in whom nephrotomy was made the hematuria persisted to such a degree that nephrectomy was necessary in 1 case three months and the other four months after the first operation. In 1 case of nephrectomy hemorrhage through the wound persisted necessitating nephrectomy two days after nephrotomy. In 1 other case of nephrotomy made four years ago the patient reports occasional hematuria in a diminished degree. The 8 patients reporting recovery following operation were operated on 1 six years, 1 four years, 2 three years, 2 two years, and 2 one year ago. In the patient operated on four years ago, hemorrhage was reported occurring a year after operation but none since then. Of the 16 cases of nephrectomy, 1 patient died elsewhere six months after operation from some unknown cause, and 1 was not heard from. Fourteen patients are living and are reported in excellent health 1 twelve years, 1 eleven years, 3 eight years, 1 nine years, 2 six years, 2 four years, 1 three years, 1 two years and 3 two years after operation. It will be noted, therefore, that nephrotomy is not to be regarded as a certain method of cure. The fact that recovery followed in 8, or 67 per cent. of the cases, should recommend it, provided the affected kidney appears quite normal on exploration. On the other hand, the excellent results obtained from nephrectomy should recommend such procedure providing the hemorrhage prior to operation had been severe enough to warrant it, that the patient's general condition was otherwise good and that the functional activity of the other kidney was previously ascertained. Of the 51 cases not operated on, we were able to trace but 44. In 26 of these cases the affected kidney was merely catheterized, with cessation of hematuria following. This cessation of symptoms remained permanent in but 4 cases. In 18 cases the pelvis was overdistended with methylene blue or colloidal silver solutions with permanent cessation of hematuria in but 3 cases. In 6 cases epinephrin (adrenalin chlorid P. D. & Co.) in solutions in 1:2,000 as advanced by Young[5] was introduced into the pelvis of the affected kidney. Recurring hematuria was reported in all cases except one treated six months ago. In one of two cases treated three years ago, hematuria was reported stopped over a period of one and one-half years. Horse-serum was injected in two cases, and human serum, as suggested by Barringer,[6] in one case with no immediate cessation of symptoms.

Treatment.—From the foregoing results it would seem advisable, as a rule, to treat essential hematuria conservatively. Needless to say, every means of diagnosis should be employed before exploration is undertaken. It has been our rule not to advise surgical exploration unless the hematuria was so marked as to incapacitate the patient or whenever evidence existed which suggested the possibility of neoplasm. The question of whether or not to explore for a possible neoplasm is one of the most difficult problems to solve in the clinical examination of hematuria. The possibility of renal tumor in a patient over 40 years of age whose general condition is below par and who has no clinical evidence of nephritis would justify surgical exploration even though the hematuria itself were not severe enough to warrant it. Exploration is not justifiable when no clinical evidence exists other than one or two spells of hematuria. In such cases ureteral catheterization or any of the various methods of renal pelvic irritation, such as overdistention, pyelography, epinephrin, etc., should first be tried, or, as has been recently suggested, the injection of blood-serum. An occasional moderate hematuria without other clinical symptoms recurring after these measures have been tried should not necessarily require any form of treatment. When the hematuria has incapacitated the patient, however, or when neoplasm is regarded as possible, exploration is indicated. The good results obtained from nephrotomy would justify its use provided nothing is found wrong with the kidney on exploration. If, on exploration, however, any evidence of previous infection or tissue-destruction exists or if nephrotomy should fail to stop the bleeding, nephrectomy is indicated.

Etiology.—Of the various etiologic factors that have been advanced to explain essential hematuria, nephritis seems at present to have the most supporters. Of recent years pathologic evidence in support of this theory has been advanced by Israel, Nichols, Kretschmer, Kapsammer, Stoerk and others. Microscopic examination of bleeding kidneys removed at operation and postmortem discloses areas of greater or lesser extent with varying degrees of nephritis in practically every case if carefully searched for. An examination of the pathologic material of bleeding kidneys removed at the Mayo Clinic shows eleven specimens. Of this number, three show nothing but a few glomeruli with cicatricial changes, one is quite normal on serial section, and the others show moderate degrees of increase of interstitial connective tissue as well as glomerular changes. None of them show the marked destructive changes found with clinical chronic nephritis. Section of kidneys removed in the last 320 post-mortem examinations of patients (Broders) who had no clinical evidences of advanced renal disease, shows some evidence of nephritis in 200 cases, or 63 per cent. In none of these cases had hematuria ever been reported and none had clinical evidence of nephritis. On comparing microscopic sections it was impossible to differentiate the character of the microscopic changes found in the bleeding and non-bleeding kidneys. It is quite evident that there must be some other factor involved which causes one of two kidneys to bleed when the microscopic changes are quite similar. Because nephritic changes are found in a bleeding kidney it does not necessarily follow that nephritis causes the hematuria.

The clinical evidence obtained on examination and observation of the after-course of patients suffering with essential hematuria does not support *any* nephritic etiology. Four of the patients operated on and three of those not operated on gave histories of hematuria of fifteen years or more prior to examination. If the hematuria were one of the earliest symptoms of nephritis the progress has been rather slow. Furthermore, the number of patients who have been entirely well five years or more since nephrectomy is not in keeping *with the* usual course of a patient suffering with chronic nephritis from whom one of two diseased kidneys are removed. Whatever the cause of the hematuria may be, if systemic, it apparently does not tend to shorten life, at least to *any* great extent. In support of the nephritic theory it has been advanced that many cases show traces of albumin or occasional casts in the urine in the interval when no hematuria is present. The routine examination of the urine of five thousand patients examined consecutively at the Mayo clinic during the past year shows a trace of albumin in 1,450, or 29 per cent. Less than a hundred of these patients had any clinical evidence of nephritis and none of them had essential hematuria. The overwhelming proportion of patients with albuminuria as compared with those suffering from hematuria demands further explanation than that of nephritic change. Furthermore, the term "nephritic" is an unfortunate one for this type of hematuria now called "essential," and tends to confuse it with the hematuria accompanying acute and chronic nephritis, which is clinically quite distinct.

[6] Barringer: Am. Jour. Urol., May, 1912.

ABSTRACT OF DISCUSSION

Dr. J. R. Caulk, St. Louis: There has been a growing tendency to attribute many of these cases of renal bleeding to nephritis, and I was glad to hear Dr. Braasch condemn this and also to hear him advocate conservatism in treatment. There is no disease—if we may call it a disease—which requires more careful diagnosis than this.

Two cases within the last year have exemplified this to me. Both of them presented clinical evidences of nephritis—albumin, casts, high arterial tension, and general evidences of nephritis—and both have cleared up immediately after pelvic injections of epinephrin (adrenalin). I think that we have to be extremely careful, for so many men are advising immediate renal decapsulation or nephrotomy. Before any such procedure is ever attempted, I think one should always try to eliminate the renal pelvis as a source of the bleeding by injections into the renal pelvis of epinephrin, of horse-serum, or of something of the sort.

Dr. O. S. Fowler, Denver: I should like to ask how many of the cases in which operation was refused were bilateral? In looking for casts in these cases of hematuria, we should never centrifuge the urine. If we centrifuge it we get so many blood-cells that they obscure all the casts. That was the case in a patient of mine. The examination was made by a competent pathologist who failed to find casts. He had centrifuged the urine. An uncentrifuged specimen showed casts.

Dr. A. L. Chute, Boston: It seems to me that a focal nephritis, not an interstitial nephritis, might explain some of these cases of hematuria. A patient I saw two years ago had had this bleeding for sixteen months. The hemoglobin percentage was low. I cut down on the kidney. I thought that I could feel a nodule in it, and therefore removed the kidney. It showed absolutely nothing in the way of a neoplasm, but it did show a condition that the pathologist said was nephritis. The patient had had a low blood-pressure. The nephritis followed a pneumonia. I do not see why we should not have a focal nephritis in cases in which the infection has cleared up and yet the pathologic change remains. That is my explanation of some of these cases.

Dr. W. F. Braasch, Rochester, Minn.: As Dr. Chute has suggested, we undoubtedly do occasionally observe cases of chronic renal hematuria with clinical evidences of nephritis, in which the bleeding simulates that of so-called essential hematuria. There is such a large number of cases, however, in which there is no other symptom than hematuria, in which, after years of observation, no clinical evidence of nephritis develops and in which little or no evidence of nephritis can be found on surgical exploration, that we must conclude that there is some factor other than slight histologic nephritis which causes *the hematuria*.

We had two cases that were bilateral, in both of which the hematuria was on one side at one time and on the other at another time. I should not regard a bilateral condition a contra-indication to operation, provided that the patient was not weakened from loss of blood and was otherwise normal. I never *have seen simultaneous* hematuria in both kidneys.

THE VALUE AND LIMITATIONS OF FUNCTIONAL RENAL TESTS *

J. T. GERAGHTY, M.D.
AND
L. G. ROWNTREE, M.D.
BALTIMORE

In ascertaining the functional capacity of the kidney, judicious selection of tests is the key to the maximum amount of information from the minimum expenditure of time and energy. The number of tests is now so large that it is impossible to utilize all in any individual case. It is unnecessary, moreover, since all of the available information is forthcoming at times from a single test or from a proper combination of a small number of tests. In order that the proper selection may be made, however, an insight into the value, limitations, advantages or disadvantages, peculiarities and significance of the findings, together with intimacy with technic concerned, is essential.

Renal functional capacity is usually ascertained in one of two ways: first, by tests of excretory capacity through the quantitative determination of various substances in the urine—dyes, methylene blue, indigocarmin, rosanilin, phenolsulphonephthalein, other chemicals—potassium iodid, lactose, sodium chlorid, urea, sugar following phloridzin and the enzyme diastase; secondly, by tests of retention through the quantitative determination of the concentration of certain substances in the blood, ions through electrical conductivity, molecules through cryoscopy, urea, incoagulable nitrogen and cholesterin.

Other tests have been proposed and advocated, but they can be absolutely discarded without loss in functional studies. On account of the approximate parallelism in the excretion of the members of the dye group, only one need be employed, and on account of its proved superiority, the phenolsulphonephthalein should be selected. Of the other excretory tests, certain ones prove of value in relation to certain types of renal disease, as will be later indicated.

Concerning the tests of retention:

The recent work of Folin and Dennis[1] indicates that the concentration of urea 0.5 gm. and of total incoagulable nitrogen 0.6 gm. per liter, heretofore considered normal, must no longer be so considered, since in sixteen strictly *normal* persons the highest non-protein nitrogen which they found was 26 mg. and urea nitrogen 13 mg. per 100 gm. blood. Slight nitrogen retention may apparently occur in *many* diseases; but in our experience in a large number of cases during the older methods and also Marshall's new urea method, we feel that no great prognostic significance is to be attached to concentrations less than 0.55 gm. per liter. Greater concentration than this together with a serum freezing-point lower than —0.6 are of the greatest prognostic importance. Evidences of retention reaching this degree we refer to as cumulative phenomena.

*From the Genito-Urinary *clinic of the* Johns Hopkins Hospital and the Pharmacological Laboratory of the Johns Hopkins University.

1. Folin and Dennis: Jour. Biol. Chem., 1910, iv, 29.

In order to make evident the peculiarities in value and limitations of these various tests it is advisable to consider them in relation to three great types of renal diseases: (1) unilateral and bilateral diseases necessitating ureteral catheterization; (2) bilateral surgical diseases secondary to obstruction in the lower urinary tract, and (3) medical diseases of the kidney.

1. In the first group it is desirable to have information in regard to three phenomena: (*a*) the total or combined renal function without ureteral catheterization; (*b*) the relative function, and (*c*) the absolute functional value of each kidney.

The phenolsulphonephthalein test is incomparable so far as total function is concerned and gives information frequently unavailable from any other source. In cases in which leakage and inhibition are absent, it furnishes in itself all of the necessary information in regard to the function of each kidney. In cases in which its excretion is markedly decreased, one or another of the retention tests should be employed.

The employment of functional tests in association with urethral catheterization is attended with two great difficulties which in certain cases make it impossible always to obtain all desirable information from any one test, namely, inhibition of function and leakage around the ureteral catheter.

Any discrepancy due to inhibition can be detected readily through the determination by phenolsulphonephthalein of total renal function without ureteral catheterization. Unfortunately the inhibition is not always equal on each side and one under such conditions is not justified in accepting the phenolsulphonephthalein or total urea from each side as the true index of the relative value of the two kidneys. In this connection, diastase and urea percentage, together with a difference in the intensity of urinary pigment and a consideration of the total phenolsulphonephthalein, are of value. Indeed, it is in this connection that urea percentage finds its greatest usefulness.

In order to obtain an accurate quantitative estimation of the function of each side it is necessary to secure complete collection of the urine. By the use of Albarran's flute-end catheter this is usually possible. In a certain proportion of cases, especially in patients with relaxed ureters, leakage does occur and sometimes in amounts sufficient to nullify the findings. Unless one repeats the catheterization, which is not always practicable, using the Garceau catheter on one side with transvesical collection on the other, knowledge of the relative functional values must be largely obtained from urea percentage, diastase and time of appearance of the phenolsulphonephthalein.

The peculiar value of urea percentage and diastase can be briefly stated. When inhibition occurs, the urea percentage and diastase have equal significance, but when secretion is free and leakage occurs, diastase is more reliable since it is not so readily affected through dilution. Phloridzin has proved of comparatively little value in our experience and adds practically nothing to the information obtainable from the other tests.

2. In the bilateral surgical diseases secondary to obstruction in the lower urinary tract, information concerning the total function alone is necessary. So far as execretory function is concerned only the phenolsulphonephthalein test is necessary. It is capable of differentiating between those cases with severe renal damage and those in which the involvement is slight. It is further capable of demonstrating a marked improvement in the renal condition following appropriate preliminary treatment and enables the surgeon to determine the cases suitable or unsuitable for operation and to select the most favorable time for surgical intervention. The urine output, urea and total solids may be practically normal, and yet the patient may be on the verge of renal failure which will certainly be precipitated by a radical surgical interference.

Other tests, most of them of recent introduction, have likewise proved of but little value. Lactose fails to appear at all in the majority of these cases, in this respect, closely resembling the absence of glycosuria following the administration of phloridzin. From either of these tests an exaggerated idea of the functional derangement is almost invariably conveyed.

Diastase usually indicates decreased function when it exists, but is not a reliable index to the extent of the functional injury. It yields no additional information and consumes more time than a phenolsulphonephthalein test and hence can be discarded.

In this group of cases, tests of retention are of great importance and one of them at least should be employed in every instance in which the phenolsulphonephthalein excretion is low. They all carry about equal significance, although the parallelism of the findings has not been sufficiently investigated. Urea and total incoagulable nitrogen parallel each other, so that only one need be employed, preferably urea determined by Marshall's method. It would seem probable that the blood-urea will furnish earlier evidence than cryoscopy. There have been three cases in our studies in which a high urea blood-content was present with a normal or practically normal freezing-point. In all three, clinical and other functional studies indicated severe renal damage. In one of these cases, with evidence of rapidly decreasing renal function, the freezing-point subsequently decreased proportionately, but the first indication of cumulative phenomena was furnished by the urea.

3. Studies of renal function in medical cases fall into two great groups: (*a*) those attempting to differentiate between tubular and glomerular involvement, and (*b*) those attempting to determine total function.

The glomerular function, according to Schlayer, is indicated by the excretion of water and lactose and that of the tubules by salt and potassium iodid. Lactose and potassium iodid both being substances foreign to the body and hence not so easily influenced by extrarenal factors, were considered to be more reliable indices than water and salt.

Schlayer and his co-workers, from their studies with lactose, water, salt and iodid tests, have attempted to divide nephritis from a purely functional point of view into four groups, namely, purely vascular, vasculotubular, tubulovascular and purely tubular. This classification has not been adopted by us for the following reasons: The evidence to be found in the literature for the assumption that lactose is chiefly excreted through the glomeruli is not convincing, and experiments carried out on the frog's kidney have demonstrated beyond doubt that the tubules are capable of excreting lactose. Our studies have led us to the conclusion that the potassium iodid test as used by Schlayer, in which he has placed greatest confidence for indicating tubular functional capacity, is unreliable. We have not encountered any cases of pure tubular nephritis. When both systems are involved, we do not feel that the tests can determine whether the tubular or vascular injury is preponderant. Mild passive congestion alone in many instances produces the same functional picture which Schlayer describes as characteristic of vascular nephritis. Consequently, a combined functional and clinical study is essential in order to differentiate two functionally similar but clinically different conditions.

At present so little is positively known or proved concerning the specific function of any individual part of the kidney that any attempt of the kind mentioned to divide nephritis is premature. Fundamental work in the physiology, involved in the secretion of substances by specific parts of the kidney, rather than the building up of a clinical superstructure on a questionable physiologic foundation, is more likely in our opinion to lead to a deeper insight into nephritis.

TOTAL RENAL FUNCTION

Doubt no longer exists concerning the ability of tests to reveal the total functional value of the kidneys. After attempting to correlate clinical and pathologic findings with the results of functional tests as simply and comprehensively as possible, the medical cases have been divided as follows: (1) cases clinically suspected of nephritis, but exhibiting practically normal renal function; (2) mild cases of nephritis without cardiac decompensation; (3) advanced nephritis without cardiac decompensation; (4) cardiorenal cases, and (5) chronic passive congestion in cardiac cases unassociated with nephritis.

In the first group, all of the tests showing a normal function, reconsideration of diagnosis becomes necessary. In cases of mild nephritis without cardiac decompensation, a normal or practically normal phenolsulphonephthalein is sometimes encountered, together with a delayed lactose excretion. These cases Schlayer would consider as a vascular type of nephritis on account of the delayed lactose excretion and the presence at times of a vascular hyposthenuria, as indicated by the study of salt and water metabolism. An identical functional picture as regards phenolsulphonephthalein and lactose may, however, be encountered in mild passive congestion of the kidneys. The lactose test may be accepted as an index of vascular disturbance, but a decreased lactose does not necessarily mean a glomerular nephritis. With a normal phenolsulphonephthalein output, tests of retention are not necessary.

In cases of advanced nephritis, the phenolsulphonephthalein is decreased, according to the severity of the lesion. Lactose is invariably delayed in this group of cases and its total suppression is of considerable prognostic significance, in contrast to its lack of prognostic value in obstruction in the lower urinary tract.

The salt test should be utilized in all severe cases, whether edema be present or not, in order to determine the capacity of the kidney to excrete salt as well as the effect on the quantity and concentration of the urine, but it should be used cautiously. The total diastatic content of the urine is usually decreased, but the extent of its decrease is not always proportional to the amount of functional injury. In all cases of severe nephritis, one or more of the tests of retention should be employed, their findings, together with the phenolsulphonephthalein, being depended on for prognostic indications. Cumulative phenomena are frequently encountered and, when present, add to the seriousness of the prognosis.

In cardiorenal cases combined functional and clinical studies are necessary in order to determine the relative responsibility of the heart and of the kidneys for the existence of the symptom-complex. Repetition of the tests is almost invariably necessary. In the presence of severe clinical symptoms, the finding of a good phenolsulphonephthalein output, along with the absence of cumulative phenomena, point to the heart as the responsible factor.

Low phenolsulphonephthalein output, together with cumulative phenomena, indicates a severe lesion of heart or kidneys, or both, and in any instance a serious prognosis. A low output of phenolsulphonephthalein, persisting after marked improvement in the cardiac condition, indicates serious renal disease.

In broken compensation, unassociated with nephritis, lactose is always delayed, perhaps markedly. Diastase content of the urine is low. The phenolsulphonephthalein, except in the severest types of congestion, is surprisingly good, while cumulative phenomena are practically never encountered. In cases in which the phenolsulphonephthalein output is low, with the first indication of cardiac improvement it immediately rises.

By means of these various functional tests, together with clinical studies, it is possible to obtain a much clearer conception of the renal condition than from clinical studies alone.

In severe renal or cardiorenal disease, associated or not with edema, the application of the salt test is of great importance.

It has been found that there is an exceptional type of case showing edema, albumin and casts, in which the general function is normal except for salt; indeed, a hyperpermeability may exist for other substances, the salt alone being delayed in its excretion.

The results of the test supply indications as to the amount of salt advisable in any individual case.

UREMIA

Uremia is a clinical condition, a syndrome, resulting from renal insufficiency from any cause. Its appearance is often sudden and unexpected; its course, acute and severe, rapidly ending in death; or chronic, lasting through months. Through functional studies, it is possible to ascertain that it is impending, even when no indications whatever of its proximity are revealed by the clinical study. With a continued failure on the part of the kidney to excrete phenolsulphonephthalein, lactose, etc., associated with the continuous, marked and increasing accumulation of urea or total incoagulable nitrogen or low serum freezing-point, one is perfectly safe in predicting the early appearance of uremia regardless of the underlying pathologic condition.

It must be remembered, in interpreting results of functional studies, that identical functional pictures carry very different prognostic significance in different clinical and pathologic associations. Extremely low functional capacity in chronic nephritis means death, whereas in obstruction in the lower urinary tract with urinary retention and back pressure the injury may be mostly functional or temporary, so that following appropriate treatment a fair or good capacity is again established.

Functional studies always find their greatest value when associated with careful clinical studies and, when properly employed, yield most valuable information from the point of view of diagnosis and prognosis and in the selection of the lines of treatment.

330 North Charles Street—227 West Monument Street.

ABSTRACT OF DISCUSSION

Dr. Louis E. Schmidt, Chicago: The only way we are going to come to any conclusions as to functional tests is by means of this comparative work of the kind which Dr. Geraghty has done. Simply to follow out the estimation with phenolsulphonephthalein is not sufficient.

Dr. W. F. Braasch, Rochester, Minn.: In my opinion, phenolsulphophthalein is the best renal functional test that we have at present. The practical value of renal functional tests, however, at least as applied to surgical conditions in the urinary tract, has not as yet been definitely determined. It is remarkable how often we see patients with prostatic obstruction who have a low phthalein excretion, even less than 15 per cent., go through an operation much better than patients with a high functional output. In fact, I do not recall ever seeing a case in which physical examination and clinical symptoms did not prove to be of greater value in determining whether or not a patient should be operated on than any laboratory estimate of renal functional capacity.

The same criticism may be made of the application of renal functional tests in the comparative estimation of the function of either kidney. With a diseased kidney on one side, a low functional estimate in the other kidney would tell us only what the functional activity of that kidney was at the time of examination, but not what it is capable of doing under corrected conditions. If the question arises, however, as to whether disease is present in one of the kidneys and if we employ the phthalein or any other functional test and get a marked diminution in the secretion from one kidney, we have evidence that disease exists in that kidney; but, if we do not get a decreased secretion, we have no positive evidence that disease does not exist. While I believe that the phthalein test is probably the best of our present functional tests, it, in common with any laboratory functional estimate, is very limited in its practical application.

Dr. John R. Caulk, St. Louis: Just one word with reference to what Dr. Braasch has said about the patient with a low output doing as well or better than those who have a high output. That, I think, is not the point. The main consideration is whether this low output is constant or not. Whether or not a man with a low output will retain it at a constant ratio under various treatment tests is a most important factor. We see persons with obstruction of the lower urinary tract, with delay in the time of appearance and marked deficiency in the total output of urine who will undoubtedly stand a prostatectomy; but we find that the output is constant. It is most important that these men have repeated tests to determine whether or not they can stand various procedures without fluctuation.

Dr. H. D. Furniss, New York: I should like to call attention to the possibility of error due to retention of the drug in these tests. I had a patient in whom the elimination of phthalein was 15 per cent. in two hours after intravenous injection; later it was 5 and again 8 per cent. In that same patient we used the lactose test and the potassium iodid test. In four hours there was cessation of excretion of lactose. That was regarded as normal. At the end of forty hours the patient ceased to excrete iodid. In all these cases a quantitative determination should be made. I think that in this case some of the lactose was retained, even though excretion had ceased. Unless we make a quantitative test we have no way to determine this. That patient had a double decapsulation, and in one week the phthalein came up to normal and has remained at that point.

Dr. Granville MacGowan, Los Angeles: Clinical experience clearly indicates to me that it is not in cases of good surgical risks that color tests are valuable but rather in doubtful cases. If you inject either indigo-carmin into a man's muscles, or phthalein into the muscles or veins, and, after a reasonable time, do not get a good show of color in the urine—a strong blue color for the carmin, in fifteen minutes, or a full rose color, within ten minutes, for the phthalein, if injected into a vein, there is something wrong with the output efficiency of one or the other kidney or of both kidneys. Almost invariably these patients will be found to have a continuous lowered output of urea and it will require well-directed effort to improve this fault, for days, weeks or perhaps months before serious surgical interference is resorted to.

Dr. Hugh H. Young, Baltimore: Those of us who have been particularly interested in the development of the phthalein test ought to explain that we feel that there is no fixed percentage that will indicate that one person is a good operative risk and another is not. There are cases which show a delayed appearance and a low percentage which are good operative risks, but these patients should be under observation for two or three weeks to determine that.

The idea that Dr. Caulk has brought out as to stability is correct. The patient has been living in the condition in which he would be after operation, and his condition is found to be stable (although the kidneys are impaired). We find quite a few patients with enlarged prostate and with low phthalein output, who remain without any symptoms of uremia. Their kidney function remains low under drainage treatment, but these patients are able to eat and go about and are quite comfortable. In these cases we feel that the condition present is a chronic nephritis and that the whole organism has buttressed itself against it and the patient will make a good recovery from the operation. It is those patients with chronic retention who have not been catheterized, and who have dilated ureters and dilated renal pelves, with low phthalein and high residual, on whom it is dangerous to operate at once. This is shown in the next few days by the rapid development of uremia after catheterization, or there will be a marked improvement, and within a few weeks the phthalein output will often be five times as good as when the first test was made, and prostatectomy is followed by no uremic symptoms. We had a case recently in which there was no phthalein excreted during four hours, and after that only a trace. That patient, after urethral-catheter drainage for five weeks, had a phthalein appearance after thirty minutes and 10 per cent. output in one hour. While he did not improve in two weeks, his condition remained stable, and he stood the operation well. You cannot give any absolutely fixed rules about this and your clinical judgment is an important deciding factor. The phthalein ought to put you on your guard and confirm your clinical observation.

Dr. H. D. Furniss, New York: I do not think that the failure of indigo-carmin to appear in fifteen minutes ought to be considered as an absolute indication of renal insufficiency. I had one case in which, after nineteen minutes, there was absolutely no elimination after intramuscular injection. After intravenous injection this patient began to eliminate it at the end of two minutes. Using phenolsulphonephthalein intravenously we obtained sixty in the first fifteen minutes after injection.

Dr. Granville McGowan, Los Angeles: I expressed myself poorly. I meant to say that, if, after an interval of fifteen minutes, when indigo-carmin or phthalein is used, a good, deep stain is not given to the urine, one had better be on one's guard about his patient.

Dr. John T. Geraghty, Baltimore: I should like to say in answer to Dr. Braasch that the determination of the renal function before any operation is valuable only in so far as it is of advantage to know anything about the renal function. If it is not necessary to know anything about the renal function, there is no necessity of doing functional tests. If, however, functional estimations give some information, and if they are of value in occasional cases, then they should be employed whenever careful work is attempted. Not infrequently information is secured in this way which can be obtained in no other manner. In double renal tuberculosis, it is not always possible to tell from the quantity of pus that is present which is the most diseased kidney. I have seen the more recently involved kidney secrete more pus than the more diseased one. A functional estimation will quickly and accurately give information regarding which is the better kidney and indicate accurately the amount of disease in each kidney. Again, functional estimations are useful in differentiating pyelitis from pyelonephritis, as in pyelitis the function is but little decreased, while in pyelonephritis the function may be seriously interfered with. From a study of the urine alone, it may not be possible to make this differentiation. This information is of value from the point of view of prognosis and treatment of cases of chronic pyelitis and pyelonephritis. If the infection is a pure pyelitis, pelvic lavage usually gives brilliant results, while in pyelonephritis the results of pelvic lavage are of only comparatively slight value. There is another class of cases whose recognition is absolutely impossible without the employment of functional tests. I refer to the infantile kidney. The urine secreted by these kidneys may be perfectly normal, but is small in amount and the presence of such an anomaly can be suspected only when functional estimations are made. Recently, we had a very striking instance of this in which a tuberculosis was present in the large, hypertrophied kidney. The function of this tuberculous kidney was six times that of the other kidney, the urine from which was perfectly normal in every respect, except that it was small in amount. These cases are probably not uncommon and it will be impossible to check them up in any other way than by a functional estimation. In the early cases of renal tuberculosis, if the disease is limited to a small area in the kidney, functional estimation may show little disturbance because there is little disturbance of function present.

One has only to glance at the literature to realize the growing interest of the medical profession in the subject of renal function and the practical unanimity of opinion regarding the value to be derived from functional studies.

THE PUBLIC HEALTH ASPECTS OF LEPROSY IN THE UNITED STATES *

RUPERT BLUE, D.Sc., M.D., D.P.H.
Surgeon General, U. S. Public Health Service
WASHINGTON, D. C.

On account of the communicability of leprosy and its mutilating effects on individuals affected, the presence of the disease in any community is a matter for concern. Leprosy is known to exist in many states and in all of our island possessions. By reason of this prevalence and the enormous volume of traffic carried on between the United States and other countries, the control of the disease becomes a problem of national importance.

PAST PREVALENCE

The infection was undoubtedly introduced into the United States from abroad, but the time of its introduction is problematical. Cases were undoubtedly imported into the Gulf States by maritime routes. The disease gained access to Pacific Coast ports through Chinese immigration, and to the north central states by means of Scandinavian immigrants. In some of these sections the prevalence of the disease evidently attracted more attention many years ago than at the present time. In Louisiana, where leprosy probably had no existence 140 years ago, the number of leprous beggars in the streets of New Orleans was so large in 1786 that the authorities had to isolate them in an institution outside of the city. The introduction of the disease in these sections has resulted in its continued propagation up to the present time. Likewise, in Hawaii, where no cases were known to exist before about 1838, the introduction of the infection of leprosy was followed by its diffusion, until now the prevalence of the disease constitutes one of the great social and political problems of that territory.[1]

On account of the incompleteness of the morbidity and mortality records generally, the extent of the prevalence of leprosy in the United States in the past can not be accurately estimated. Its extent was so large, however, as to claim the attention of the authorities in New Orleans as long ago as 1786, the authorities of San Francisco in the early seventies and other states at later dates.

There is record of the occurrence of cases of leprosy from time to time in many states. Within the past fifty years the occurrence of the disease in the United States has attracted most attention in the south Atlantic states, Louisiana, the north central states and the Pacific Coast states. In 1866, the disease was recognized as having reappeared in Louisiana. In 1890, Gronvald reported the existence of sixteen cases in Minnesota, and stated that the disease had prevailed there for fifty years. He estimated the following year that about one hundred and sixty lepers in all had immigrated into Wisconsin, Iowa and Minnesota. During the ten years prior to 1883, fifty-two lepers were admitted to hospital in San Francisco.

From our more recent knowledge it appears that these sections have been foci of leprosy up to the present time. In the report on leprosy in the United States submitted by a commission of medical officers of the U. S. Marine Hospital Service the presence of 278 cases of leprosy was shown but, as stated by the commission, this did not represent a complete census. Of the 278 cases reported 145 individuals were native-born, 120 were foreign-born, and the birth-places of the remaining thirteen could not be determined. These cases were scattered through twenty-one states and territories, showing the broad distribution of the disease throughout the country. In over 73 per cent. of the cases recorded the affected persons were at large, only seventy-two being isolated and provided for by the states or cities in which they were located.

PRESENT PREVALENCE

In 1909, by means of correspondence, steps were taken to ascertain the occurrence of leprosy in the United States and its dependencies. As a result, records were obtained of 139 cases located in thirteen states and the District of Columbia, 764 in Hawaii, 17 in Porto Rico, 2,330 in the Philippine Islands and 7 in the Canal Zone. These cases, however, were only those "officially recognized," and it was regarded as altogether probable that many cases had not been included in the compilation.

In studying the regional distribution of the disease, four zones of infection could be distinguished, viz., the Atlantic seaboard, the Gulf Coast, the Pacific Coast and the north central states. In the Gulf Coast zone three foci of infection were recognized as being active. On the Atlantic and Pacific coasts a variable number of cases were occurring, and in the north central portion of the country the disease appeared to be decreasing.

By means of correspondence last year (1912), steps were again taken to ascertain the number of officially recognized lepers in the United States and its dependencies. This inquiry referred especially to the number of new cases reported during the calendar year 1911 and to the number existing Jan. 1, 1912. As a result, a total of 146 cases was reported in the continental United States, forty-one of these individuals having been apprehended during the calendar year 1911.

The total number reported necessarily represented only a portion of the cases occurring, as in many states the disease is not notifiable, and in others, the requirement of notification is difficult of enforcement.

Leprosy has been specifically made a notifiable disease in the following eighteen states and the District of

[1] New York Med. Jour., March 24, 1888, p. 322.

Columbia: Alabama, California, Connecticut, Florida, Idaho, Illinois, Indiana, Iowa, Massachusetts, Nebraska, New Jersey, New York, Oregon, Pennsylvania, South Carolina, Utah, Washington and Wisconsin. At that time the disease was also notifiable in Hawaii, Porto Rico and the Philippine Islands, and on the date mentioned there were reported in these jurisdictions respectively, 696, 28 and 2,754 cases, making a grand total of 3,624 officially reported cases in the United States and its possessions.

In Michigan, a regulation of the State Board of Health specifies that cases of leprosy shall be reported for statistical purposes. In certain other states the laws require that cases of all infectious or contagious diseases shall be reported, and among these leprosy would naturally be included. In the absence of a statement of the diseases that shall be construed to be infectious or contagious, however, it would appear to be left to the personal opinion of each practicing physician as to which diseases came properly under a classification, and were, therefore, notifiable. Under these conditions it could only be expected that the reports would be incomplete.

Although the number of cases of leprosy reported by the state authorities as present Jan. 1, 1912, was only 146, whereas, the commission above referred to found 278 in 1901, it cannot properly be inferred that there is a lessened prevalence of the disease. The 146 cases reported as present the first of last year were, with one or two exceptions, isolated and under the control of state or local authorities. These 146 cases are, therefore, probably comparable with the seventy-two cases reported in 1901 as isolated and provided for by states or cities.

From this brief summary, it is evident that leprosy is widely distributed in the United States, and, while the total number of cases recorded is trivial in relation to a total population of over 90,000,000, a public health problem of national importance presents by reason of such distribution, and the numerous possible foci of infection that exist.

FEDERAL MEASURES IN RESPECT TO LEPROSY

On account of the loathsome, contagious character of leprosy, the helplessness of persons so afflicted, and the public dread of its introduction and spread in the United States, the disease has been made the subject of consideration and certain official actions by the federal government for many years. The first object was to prevent the introduction of the disease, and on Dec. 23, 1889, a regulation was issued by the Secretary of the Treasury forbidding the entry of any vessel to any port of the United States without a certificate from the proper officer that no case of leprosy was found on board said vessel, or in case one had been found, that it had been removed from the vessel and detained at the quarantine station. This regulation provided that lepers so apprehended should be permitted to depart on outgoing vessels bound to the foreign country from which the leper last sailed.

Although this regulation was superseded by others subsequently issued, practically its provisions are in force at the present time.

In accordance with the quarantine act of Feb. 15, 1893, no alien who is a leper is allowed to embark for the United States from foreign ports; and, under this law the following special regulations have been issued for observance at domestic ports to prevent the introduction of leprosy:

129. Vessels arriving at quarantine with leprosy on board shall not be granted pratique until the leper and his baggage have been removed from the vessel to the quarantine station.

130. No alien leper shall be landed.

131. If the leper is an alien passenger and the vessel is from a foreign port, action will be taken as provided by the immigration laws and regulations of the United States. And to this end the case shall be certified as a leper and reported to the nearest commissioner of immigration.

132. If the leper is an alien and a member of the crew and the vessel is from a foreign port, said leper shall be detained at the quarantine at the vessel's expense until taken aboard the same vessel when outward bound. Such case of leprosy should be promptly reported to the collector of customs at the port of arrival of the vessel, and the collector shall exact a bond from the vessel for the reshipment of the said alien leper on the departure of the vessel.

The immigration laws forbid the landing of immigrants afflicted with loathsome, contagious diseases, leprosy being included in this class. Adequate authority thus exists for the exclusion of leprous individuals, but on account of the long period of incubation of the disease and its extreme chronicity, the possibility of the entry of cases must be admitted.

Fortunately, however, the immigration laws provide that any alien afflicted with leprosy may be deported at any time within three years after the date of his arrival, provided the disease existed prior to landing. The federal government is thus able to exercise authority over leprous aliens for three years after their arrival, and, by deportation, to relieve the state of the burden of their care.

Under the quarantine act of Feb. 15, 1893, the federal government through the Public Health Service also exercises jurisdiction over the transportation of lepers in interstate traffic. In a regulation of June 24, 1909, issued in accordance with this law, authority was granted for the acceptance of lepers for transportation under proper supervision when *en route* to a seaport for deportation or to a designated place for care and treatment, the observance of proper sanitary precautions being required while *en route*.

In a regulation of May 15, 1912, common carriers are prohibited from accepting for transportation in interstate traffic any person afflicted with leprosy until a permit has been obtained from the Surgeon-General of the U. S. Public Health Service describing the restrictions that shall be observed. This regulation which was issued by the Secretary of the Treasury also prohibits lepers from accepting transportation in interstate traffic until the permits above mentioned have been obtained, and unless such lepers shall have agreed in writing to comply with the restrictions specified. The regulation further provides that lepers who have left the state where they reside may be detained and returned to such state, or removed to such federal quarantine station as the Secretary of the Treasury may designate, the conveyance occupied by them during such removal to be closed after being vacated, and disinfected.

From the foregoing it will be seen that control has been exercised to prevent the introduction and spread of leprosy. The leprosy problem, however, relates more particularly to the care and segregation of the cases that are discovered from time to time in different parts of the country, and who are in reality under the jurisdiction of the state authorities.

As previously stated, efforts were made in 1901, 1909 and 1912, to determine the number of such cases. These investigations and the hardships experienced by lepers on account of the morbid dread of the disease on the part of the public generally, have emphasized the need of a rational and humane method of care of persons so afflicted.

In his annual report of 1891, the Surgeon-General of the Public Health Service advocated a national leper hospital to be maintained by the federal government for the care of these unfortunates. The circumstances giving rise to the need of such an institution were strikingly set forth by the president of the Pennsylvania State Board of Health as long ago as 1890 in the following words:

> It is the consensus of opinion that persons suffering from leprosy, on account of its peculiar nature, its chronic character, and the abhorrence with which the public view it, should be removed from society and humanely cared for and treated in places especially set apart for this object. It is impracticable for towns or cities, or even states to provide such places, on account of the expense, the number of cases not being large enough to warrant the necessary expenditure. And what is finally to be done with the lepers that are now ill provided for, and those that will be discovered in the future? They cannot be treated in general hospitals except for a very limited time. It is difficult to return them to their native countries, though most of them are unnaturalized foreigners. Where there are hospitals for contagious diseases (and few places have such hospitals) temporary provision might be made for them. Here they must necessarily be secluded in unfrequented apartments, denied intercourse with relatives and friends, shut out from the world, denied the freedom of outdoor exercise because of the popular aversion to the disease, and doomed to a life of suffering, and, what is worse, of mental anguish over their deserted and hopeless state. What is to become of lepers who may happen to be discovered in places which have not even such inadequate means for detention?

Practically the same situation and the questions arising from it exist to-day. Federal, state and municipal health authorities have for years urged the establishment of a national leper home. In 1905, a bill was introduced into both houses of congress to provide for such an institution for the segregation and care of lepers by the U. S. Public Health Service. The bill was passed by the Senate and favorably reported by the House Committee on Interstate and Foreign Commerce, but failed of passage in the house, presumably because of the fears of certain members that the institution might be located in their state.

Objections have arisen to the care of lepers even at federal quarantine stations, and officials have demanded the removal of cases to some other place outside of their state.

The reasons which prevented legislation and which demand removal of lepers as above mentioned will be powerful factors in the postponement of provisions for the federal care of lepers. Nevertheless, humane segregation is necessary, and ultimately will have to be provided if the states are to be relieved of a burden, and the extension of the disease prevented. In the meantime the Public Health Service is studying leprosy with the hope of evolving methods of prevention and cure, and the states and territories will necessarily provide such care and treatment as is possible.

INVESTIGATIONS OF LEPROSY

By an act of March 3, 1905, Congress provided for the investigation of leprosy with special reference to the care and treatment of lepers in Hawaii. In accordance with this provision, a leprosy investigation station was established on the island of Molokai, and a branch station located in connection with the Leper Receiving Station at Honolulu. The bacillus of leprosy has been cultivated there, and Clegg, who discovered first a method of growing the organism, is now there studying the products of the organism and its influence on man and the lower animals. Epidemiologic and clinical studies are also being carried on, and these investigations will be continued until definite results are obtained.

The work is in charge of Dr. G. W. McCoy of the Public Health Service.

STATE PROVISIONS AGAINST LEPROSY

The leprosy problem has been as difficult for the states and territories as for the federal government. The disease is mentioned in the laws of eight states, the District of Columbia, Hawaii and Porto Rico, and the regulations of the state boards of health of sixteen states. In practically all reporting and segregation of cases is required, but there is considerable difference in the methods employed.

In Minnesota, self-isolation in the home is required. In Louisiana, on the other hand, every known leper is required to become an inmate of the leper home located in Iberville Parish. Massachusetts maintains a leper colony on Penikese Island, and the city and county of San Francisco maintains a leper hospital on the outskirts of that city. In other states in which lepers are domiciled quarantine is maintained either by state or local authority. In Hawaii, Porto Rico and the Philippine Islands leper colonies are maintained, and segregation is more or less effectively enforced.

In Texas, $40,000 was set aside in 1909 for the erection and maintenance of a leper home, but on account of opposition of localities to its erection, nothing has been done. This is a striking example of the aversion on the part of the public to lepers and the difficulty of providing for their care. In consequence of such difficulties, the occurrence of cases in some jurisdictions has been purposely ignored, while in others they have been driven or allowed to depart to some other state.

On account of the recent notoriety attending the transfer of a leper from Washington to New York, the attitude of the latter city in respect to such cases is generally known. Although its population is congested, and presumably good opportunities would be afforded for transmission, segregation is not practiced.

THE POSSIBILITY OF THE SPREAD OF LEPROSY

By some the presence of leprosy here and there in the United States is held to be of little consequence in comparison with the occurrence of other diseases, such as tuberculosis and typhoid fever. Nevertheless, it is a menace to the public health and deserves special consideration because of the possibility of the spread of the infection, the hopeless nature of the disease and the aversion of the public to persons so afflicted.

While the spread of leprosy in recent years has not been marked it must be remembered that cases of the disease have developed from time to time in American-born persons, some of whom had not been outside of the United States. Of the 278 lepers recorded in 1901 and previously referred to, 145 were American-born. By reason also of our increased world relations, and interests in the Philippine Islands and other possessions, there is greater danger than ever to fear the introduction of leprosy by returning American citizens.

Large numbers of soldiers, sailors and civil employees spend prolonged periods abroad, particularly in the Philippine Islands, where there is decided danger of contracting the infection. The disease may not manifest itself on these persons for years after their return, but new foci of the disease may thus be created.

In considering the epidemiology of leprosy, the incubation period and duration of the disease must be reckoned in years and in decades rather than in days and months. The incubation period is prolonged, and the duration of infection extends throughout the life of the patient.

These facts taken in connection with our knowledge of the rise and fall of epidemics in the past suggests the possibility of a greater prevalence of the disease fifty or one hundred years hence, unless appropriate preventive measures are instituted and enforced.

MEASURES OF CONTROL NECESSARY

Leprosy should accordingly not be regarded as a negligible factor in public health administration, nor should it continue to be an object of unreasonable aversion on the part of the public. Education is necessary to overcome the latter. Public health officials and physicians, therefore, should systematically teach the people the nature of the disease, the extent of its contractibility and above all the humane treatment that should be accorded lepers.

Every case of leprosy should be promptly reported to the proper health authority and, wherever necessary, the laws should be so amended and penalties provided for non-observance.

All lepers should be segregated in such manner as to prevent the spread of the disease, but the necessary segregation should be enforced so as to promote the comfort and happiness of those so afflicted.

On account of the difficulty of providing these conditions in towns, counties and states where single cases of leprosy occur, and because of consequent inadequate methods of control, I believe there should be established under the Public Health Service a national leper home for the care and treatment of such cases as may be turned over by state and local health authorities for the purpose.

CLINICAL ASPECT OF LEPROSY *

EDUARD BOECKMANN, M.D.
ST. PAUL, MINN.

Our medical text-books tell us that we have many lepers in this state and that they are immigrants from the Scandinavian countries, particularly from Norway. Our lepers are gradually dying out and there are not enough left for clinical demonstration even if all were at hand at this meeting. A few cases will give us only a faint idea of the clinical aspect of this exceedingly varying disease with its different forms, many stages, all possible degrees, irregularities, asymmetry, complications and great variability in the final mutilations. One case is not like another and a complete clinical demonstration would mean hundreds—and we have not got them.

As everyone knows, leprosy appears in two clinically different and, when developed, sharply defined forms. In both forms, a macular cutaneous eruption is the first symptom—the initial lesion, which probably exists, having never been discovered—and in this stage it might be questionable which special form of leprosy will develop. This prodromal or eruptive stage is not seen in the leproseries, where the patients come when the disease is fully developed and recognized. People familiar with the disease in districts where it is endemic, will observe a change in the attitude of the patient, who is stupid, drowsy, feverish, depressed, disinclined to work, complaining of general malaise, pains in the limbs and soreness. The face, particularly the region of the superciliary ridge, is puffy and assumes a dusky hue, especially noticeable during changes of temperature. A dirty yellowish discoloration of the circumcorneal part of the sclera, which together with the cutaneous eruption gives the patient a melancholy, sorrowful expression, has always in leprous districts been regarded with suspicion by the people. When the cutaneous eruption is well established, it is usually easy to know which form of leprosy will develop, and this is a matter of no small importance to the sick, as in one form of the disease life is much shorter, the patients suffer much more and are less frequently, if ever, cured than in the other form.

Authorities on the subject have in vain tried to find a short, concise and descriptive name for all the different phases of the disease, but they have not even succeeded in agreeing on a universal name for the two groups or forms of leprosy. Boeck and Danielssen's "elephantiasis graecorum tuberculosa," "anesthetica" and "tuberculo-anesthetica" or "mixta" have by Hansen and Looft been supplanted by "lepra tuberosa" and "maculo-anesthetica," which at present are the official names in Norway. Bidenkap prefers "lepra tuberosa" and "lepra nervorum." In my writings I have used the names "tuberous" and "macular" leprosy. All these names are inadequate and also immaterial, if we only keep the two forms separate as clinically very different. In Norway it is customary to speak about nodular and smooth leprosy—*knudet og glat Spedalskhed*—which after all, may be good practical names. Mixed leprosy should be stricken out, as the two forms never appear simultaneously in the same person from the beginning. It is not rare that either form ultimately is transformed into or complicated with the other form; the disease never originates as mixed leprosy.

TUBEROUS LEPROSY

Tubercular or tuberous leprosy begins with an eruption, gradual or acute, of usually not very distinct, pigmented spots of variable size without perceptible infiltration. Livid in the beginning, they assume, after a while, a brownish color. In contradistinction to the spots in macular leprosy, these spots are not sharply defined, neither do they appear in exactly the same locality, although the face, the eyes, ears and the extremities are places of predilection for the eruptions in both forms. It can be laid down as a rule, to which there are few exceptions, that eruptions in the tubercular form do not attack the scalp, the trunk, the sexual apparatus, the palms of the hands and the soles of the feet.

After the stage of eruption comes gradually the stage of diffuse or nodular infiltration of the spots—the formation of lepromas, which name designates the leprous products, wherever they are, in the skin, the subcutaneous tissue, the eyes, the mucous membranes, the nerves, etc. The skin covering the lepromas becomes dense and glossy; the consistency of the lepromas is solid, the shape being usually that of a globe cut in half, sometimes oblong.

The size varies from a couple of millimeters to extensive masses, when they become confluent; the color varies from reddish, yellowish to brownish and even to black. The lepromas do not itch and are indolent except in acute eruptions. At the site of the lepromas the hair will fall out and the sudoriferous and sebaceous glands will atrophy. When the tuberous lepromas in the face are numerous, large and confluent, with furrows between them, we have the so-called *facies leonina* (lion face). Otherwise we find all degrees both as to extensiveness and intensity. Hansen and Looft mention that they have seen lepromas so small, discrete, few and so little characteristic, that the diagnosis had to be made by microscopic examination of an excised piece. Sometimes lepromas in the skin cannot be seen but may be felt, when they extend into the subcutaneous tissue instead of outward. Therefore, palpation of the skin is just as necessary as inspection.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

The lepromas in the skin, when once developed, will for the most part remain stationary for years; they grow but little if any at all. Sooner or later, however, this slow development is interrupted by more severe outbreaks, the so-called eruptions. The eruptions, which Hansen and Looft look on as a result of auto-infection, mean an acute outbreak of new lepromas in the old as well as in new places. The general health, which heretofore has been fair, suffers under high fever, general malaise and pains; the patients stay in bed from days to months. The eruptions on the extremities have a great likeness to erythema nodosum, sometimes even to pseudo-erysipelas. The disease progresses always through eruptions in shorter or longer intervals. When the eruption fever is over, the patients pick up quickly. They never die in the attacks, but they come out more leprous than before, having at least more leprous manifestations. The number of eruptions in a patient is variable.

The lepromas may grow so luxuriously that the epidermis breaks or is cast off. The exposed surfaces cause the patients great discomfort and they seek relief in plastering up the often numerous places, which are little disposed to septic infections. Erysipelas, which was endemic during my time in the leproseries, got hold of many and carried off some of the patients.

After several years the stage of diffuse or nodular infiltration is followed by a stage of absorption or ulceration. The lepromas soften exactly in the middle of the base and the surface sinks in. Or they break open with expulsion of the softened contents and an ulcer results, which finally heals with a depressed, radiating, white or pigmented scar—the leproma is healed.

The patients usually die in this stage from complications or intercurrent diseases after an average illness of eight or nine years.

Tubercular leprosy attacks the eyes in 75 per cent. of the cases—the lids, conjunctiva, cornea, sclera, iris and ciliary body, but never the inner eye. I shall not take up space by detailing the clinical aspect of the eye affections in this form, however interesting they may be; I have described them repeatedly elsewhere. I shall only direct attention to the dirty discoloration of the sclera, often found in the beginning of the disease. This, together with a faint obscuration of the upper part of the cornea and the already mentioned dusky hue of the region of the superciliary ridge are early and sure symptoms of advancing tubercular leprosy. Blindness from invading corneal lepromas and leprous iridocyclitis is not uncommon. It is a consolation to the misery, that the advance of the corneal lepromas can be arrested for a long time by establishing a scar between the leprous and the clear cornea by performing a keratotomy. Finally, however, if not absorbed, the lepromas will transgress the scar and blind the patient.

The tubercular leprosy may also attack the mucous membranes of the nose, mouth, tongue, pharnyx and larynx. Only the anterior soft part of the nose is affected. The septum may ulcerate and the tip of the nose will sink in. The soft part of the nose may disappear entirely, leaving a cavity. The bony structures of the nose are never affected. Lepromas are often found on the mucous membranes of the lips, the mouth, the soft palate, the pharynx, epiglottis, larynx and vocal cords. Tracheotomy is not a rare operation in these cases. Many patients carry a tracheotomy tube and are not worse off for it, as they already were incurably aphonic.

The lymph-nodes are always enlarged. The swelling is indolent and never suppurating.

The peripheral nerves are always affected in this form of leprosy—not from the beginning, but always in the later course of the disease. The facial, radial, median, ulnar and peroneal nerves are always invaded. The lepromas of the nerves are palpable at places of superficial exposure; of the median nerve at the wrist, of the ulnar nerve at the inner condyle, of the peroneal nerve where it swings around the head of the fibula. Pains, intense pains, requiring relief by morphin hypodermatically, and anesthesia result from the leprous neuritis. Anesthesia is not so marked as in the maculo-anesthetic form, but can usually be easily demonstrated in the peripheral parts with the advancing disease.

The tubercular leprosy also attacks the testicles, the liver and the spleen. These affections have only pathologic interest, however, and are of no clinical significance whatsoever.

A tubercular leper rarely, if ever, recovers; it happens oftener, if he survives the different stages and all lepromas have disappeared, leaving scars and other deformities, that he turns into a pure anesthetic leper with mutilations as the final stage of the disease. The lepromas of the nerves are the last ones to disappear and if they do ever disappear, the vitality of the nerve itself has disappeared with them but, fortunately, never completely.

The clinical aspect of this form of leprosy is too characteristic for diagnostic errors. If ever in doubt, examine for lepra bacilli, which is easy, as they are always present and in great numbers in all lepromas. No other disease should ever be confounded with tubercular leprosy.

MACULO-ANESTHETIC LEPROSY

It seems strange that the same germs in the same locality can produce two distinctly different forms of leprosy, the one having no external resemblance whatsoever to the other. Lie, Hansen's successor in Norway, intimates that the difference between the tubercular and maculo-anesthetic forms consists in a greater wealth of lepra bacilli in the first and a greater reaction to the few bacilli in the last form. The result is that the erythematous eruptions in the first form go on to lepromatous infiltrations, while the erythematous eruptions in the second form gradually fade away. In the nervous system, the difference is not so conspicuous, but the proportionately few bacilli here, the complete disappearance of the bacilli in some cases, the intense neuralgias and the deposits of lime salts in the nerves are indicative of the same condition here as in the skin; fewer bacilli and greater reaction.

The initial lesion, if such exists, has not yet been found. There are indications that the mucous membranes of the nose where lepra bacilli often are found in the secretions, might at least be one of the places where the bacilli get entrance to the system through inoculation in nose-picking or otherwise. But, to quote Hansen: "the greater the ignorance, the livelier the imagination."

Although there are a few cases on record in which no cutaneous eruptions ever were observed, the claim is general that maculo-anesthetic leprosy is always ushered in with an eruption of isolated, erythematous spots which, in contradistinction to the tubercular form, may be found in any locality with the exception of the scalp—on the face, on the cornea, along the course of the spinal nerves. The maculae are of different sizes, from 2 to 3 cm. in diameter to much larger. They are reddish at first, become more and more pigmented and after a while are yellowish to brownish. Their form can be round, oblong, irregular or annular; their margins are sharply defined; they are either flush with the skin or plainly elevated, sometimes desquamating and always hyperesthetic to begin with, anesthesia being a later symptom. The maculae may spread, become confluent and form landscape-like figures. A rather symmetrical distribution is the rule, from which there are many exceptions. The maculae will last from a few days, even less, to several months. They fade from the center toward the periphery, leaving for a time annular forms; they can disappear entirely without leaving perceptible marks or they can leave behind more or less anatomic changes, demonstrable so long as the patient lives; in some cases the skin may become entirely atrophic, transparent, and thin as a cigarette paper. New eruptions may follow at later periods either in the old or in new places.

Swelling of the lymph-nodes is usually present and will remain long after the eruptions have disappeared.

With gradual disappearance of the cutaneous eruptions the leprous neuritis, which progresses from the superficial nerves of the maculae toward the center and later as degenerative neuritis toward the periphery where there never was any eruption, will predominate in the clinical aspect. Maculous leprosy gives way to anesthetic leprosy and the anesthesia is the key to the situation.

Lie, who has made extensive and excellent studies of the leprosy in the spinal cord and the peripheral nerves, finds that leprous polyneuritis is of two kinds; the neuritis of the peripheral parts of the nerves is at a certain stage of the disease due to the presence of lepra bacilli, while the neuritis in the most central parts of the nerves, where no bacilli could be found, must be of secondary, degenerative nature, resulting from the influence of the lepra bacilli on the peripheral nerve-ends. When the bacilli first have invaded the nerves, the leprous process proceeds with more or less rapidity toward the central nervous system. The advance of the bacilli stops as a rule about the middle of the arm in the ulnar nerve; still more peripherally in the median and radial nerves and in the middle of the thigh in the sciatic nerve. On this leprous stretch the nerves are thickened and can be felt, where they are superficial, particularly at the inner condyle of the humerus and at the head of the fibula.

Lie found the changes in the more central parts of the nerves where bacilli never were found, less pronounced than in the peripheral parts, but always in proportion. The degenerative changes were characteristic by the absence of that hypertrophied connective tissue, which accompanies the lepra bacilli and by the presence of very thin nerve-fibers, which he considers atrophic, the nerve trunks becoming thinner than normal as a result. These degenerative changes can be traced clear to the roots on one side and to the periphery on the other side—descending degeneration along the nerves, which were not invaded by the lepra bacilli. The anterior roots were, however, undoubtedly less affected than the posterior.

Lie found the spinal ganglia seldom normal. He found hyper-pigmentation in the ganglion cells; the nuclei had often disappeared and the protoplasm presented different degrees of tigrolysis and pyknosis. Bacilli were found in nearly all the tubercular cases and in a great number of the anesthetic, partly in normally appearing ganglion cells, partly in degenerated ones. Lepra bacilli were rarely found in the tissue outside the ganglion cells.

In the gray substance of the spinal cord Lie found changes analogous to those in the spinal ganglia, only less pronounced and with fewer bacilli. The most constant changes were found in the white substance, particularly in the dorsal columns and the posterior roots, whereas the spinal cord seems to be a less favorable bacilli.

He also found bacilli in the central nervous system in all cases where he found them in the periphery. He considers the central nervous system a place of predilection for the bacilli, particularly the spinal ganglia, whereas the spinal cord seems to be less favorable domicile.

The leprous and degenerative changes in the spinal cord do not, as heretofore believed, belong to the anesthetic form of leprosy alone; they appear in all somewhat older forms—even typically tubercular—when the peripheral neuritis has reached such an advanced stage, that we can demonstate anesthesia and atrophy in the periphery.

CLINICAL ASPECT OF NERVE LEPROSY

The patients are more or less tortured by neuralgias, generally present in the extremities and usually of sufficient severity to justify hypodermic relief. We had in my time many morphin habitués.

Anesthesia is a constant and the most characteristic symptom. It may proceed to complete loss of the tactile and thermal sense. Anesthetic areas are generally found on the forearms and hands, on the legs and feet, on the trunk and on the face and eyes. They are usually demonstrable at the site of the eruptions, but will also be present in parts supplied with degenerated nerves.

Vesiculation or pemphigus eruption is characteristic for this form of leprosy, but is absent in the tubercular form. Vesicles are sometimes present in the beginning of the disease simultaneously with the cutaneous eruption; ordinarily they appear when the anesthesia is well developed. Vesiculation is considered a trophoneurotic symptom. It is to my mind questionable if vesiculation is not often the result of traumatism, such as exposure to protracted pressure or intense heat, the patient not being able to control either because of the loss of sensation. Whatever may be the cause, vesiculation often comes on suddenly; the patient wakes up with one or more bullae. The contents of these bullae are serous and devoid of lepra bacilli. They usually burst soon and the places heal with first, a pigmented, later white scar. Sometimes septic infection sets in, deep ulcerations following. This is particularly seen on the hand and under the ball of the foot (*mal perforant de pied*).

Acute rheumatic affections of the joints, not seldom observed, are also regarded in the light of trophic disturbances, although they may be explained as metastatic affections. The joint affections belong to the earlier stages of the disease, appear mostly simultaneously with the maculous eruptions and disappear with them. They may repeat themselves and leave some stiffening of the joints.

Other trophic disturbances in advanced cases are edematous, pale glossy, slightly desquamating, atrophic skin (white leprosy) devoid of hair, sudoriferous and sebaceous glands; in old cases, hyperkeratosis has been observed, usually symmetrical, on the anterior aspect of the crura, on the backs of the hands and the soles of the feet. Malformations of the nails, which become either thickened or brittle, fissured or thinned and decreased in size, are also trophic manifestations.

Atrophy of the subcutaneous tissues, the muscles and the bones are constant manifestations and are looked on as trophic disturbances. The muscular atrophy might, however, result from inactivity due to progressive muscular paresis. This muscular paresis and atrophy run parallel with the progressive anesthesia.

In the stage of resorption, which after many years follows the stage of eruption and leprous neuritis, the disease may clear up and a practical cure be effected with more or less complete return of sensory and muscular activity, but sclerosis of the nerves is the usual result, after all the leprous products, including the bacilli themselves, have disappeared, and permanent anesthesia with all its sad, often extremely pathetic consequences, will follow. The leprosy is cured, but the cure is dearly bought on account of many horrible mutilations such a cure so often brings. This is the final stage in many cases—the stage of mutilations (lepra mutilans), which might cover many years, until complications or intercurrent diseases end the miserable existence.

The facial and trigeminal nerves are almost constantly affected but seldom to the same degree. Paresis and atrophy of the muscles of the face and anesthesia of the eyes will produce a very characteristic clinical picture. The face loses its expression and mimic, winking becomes more seldom and the look is sorrowful. It may happen that the masseters become so lame and atrophic, that the lower jaw sinks and has to be held up artificially. Paresis of the orbicularis oris causes ectropion of the lower lip, with difficulty or even impossibility of closing the mouth, while the saliva constantly dribbles away. Paresis of the ocular orbicular muscles makes insufficient closure of the lids; paralytic ectropion of the lower lids with eversion of the puncta will result and cause epiphora and xerosis of the lower part of the cornea with ulceration, perforation and its further consequences unless remedied by medial tarsorrhaphy, an operation which has saved many eyes and is consequently very popular.

The motor nerves of the eyeballs are probably sometimes also affected, as the excursions of the globe might be more and more limited and even go on to complete paralysis—the bulb standing perfectly still in the middle of the orbit.

The ocular affections in anesthetic leprosy I have repeatedly described in papers and dissertations in Norwegian when engaged in the leproseries. I think I have proved to universal satisfaction, that the above-named affection in the lower part of the cornea is entirely due to xerosis and not at all to neuroparalysis.

The anesthetic eyes stand operations of magnitude as iridectomies, cataract operations and tarsorrhaphies just as well as normal eyes and artificial anesthesia is superfluous. Xerosis of the cornea may take in the entire surface and destroy the eyesight; it may also be complicated with a real leproma and followed by lepromas elsewhere.

As to the extremities, the anesthesia, paresis and atrophy will lead to most characteristic pictures. Atrophy of the interosseal muscles will make the interosseal spaces show up as furrows. The muscles of the thenar and hypothenar eminences waste away with disappearance of the natural roundness of these parts. Gradually most of the muscles of the hands will atrophy, then those of the forearms, and, lastly, even some of the arm. The corresponding muscles of the lower limbs undergo the same atrophy. The muscular paresis, however, never becomes complete. The lepers can always make good use of their hands and feet and do astonishingly clever work with their crippled extremities. They can sew, knit, spin, make nets, shoes, brushes, combs and do blacksmithing and carpenter work. And they sell their products without any ill results to their customers. Their walk is characteristic; they lift their legs with effort because of the muscular weakness.

Gradually the real mutilations appear. Contractures of the hands and feet develop. The hands become claw-like (*main en griffe*). The first phalanges are dorsally and the rest of the fingers volarly flexed. This malformation is also present in the feet, but generally to a lesser degree. But these are not all the mutilations to which these lepers are subjected. With the progressive anesthesia follow frequent and almost unavoidable exposures to injuries, infections, and ulcerations. They bruise, cut, burn or squeeze their hands or fingers very frequently; they stand on their feet so long that the circulation under the heels and balls of the feet is interrupted with resulting vesiculation, crushing of the bullae and infection; or the toes and feet are injured and infected in all sorts of ways. Purulent periostitis often results; the bones of the fingers, toes, hands and feet are laid bare and they are expelled in necrosis if not professionally removed, leaving awful mutilations.

The final result often is that all fingers are wanting on the hands; that only small, soft, disfigured prominences provided with crippled nails are left behind on the otherwise atrophic middle hand; that the toes are cast off, the metatarsal bones atrophy, and that the tarsal bones also necrose, so that the foot finally appears as a pyramidal lump or pillow at the lower end of the tibia.

Indurated ulcers on the legs, like varicose ulcers, are often observed; they heal under appropriate treatment.

The mucous membranes of the nose, mouth, throat and pharnyx do not seem to suffer and the olfactory, acoustic and optic nerves seem to remain intact. Hansen and Looft, however, claim that the senses of smell and taste may be reduced, even entirely gone in cases of very pronounced facial paralysis. I remember, though, a case in one of the leproseries in Bergen, a blind man, terribly mutilated otherwise, going around enjoying his snuff-box—his only pleasure. His hands were completely anesthetic; with his tongue, he ascertained if the snuff was there and he managed to get it into the right place. He was in all his misery a happy man—decidedly so when a "hypo" was added to his snuff.

Gastric Ulcer and the Appendix.—There is now no longer any doubt in my own mind that the commonest site of a "gastric ulcer" is in the right iliac fossa. That is to say that in the majority of cases in which the most erudite teaching of the most astute German physicians would justify or compel a diagnosis of ulcer, the patient is suffering from a lesion elsewhere, and more often than not from a lesion in the appendix. —Sir Berkeley Moynihan, Address in Surgery, Brit. Med. Assn., 1913.

THE DERMATOLOGIC ASPECTS OF LEPROSY *

ISADORE DYER, Ph.B., M.D.
NEW ORLEANS

In undertaking a brief presentation of the dermatologic side of leprosy there stands out the prime question: From what point of view? To a mixed audience, not technically trained in terms of dermatology, the subject must appeal most from the diagnostic point of view, and in this apprehension of the subject a brief synopsis of salient skin leprosy is to be presented.

There is no stereotyped classification of leprosy, and even when the attempt is made to make distinctive groups of types of the disease the exceptions are more numerous than the rule.

It is easier to study the skin evidences of leprosy on the presenting lesions than to try to fix the types in which any complex of symptoms may be looked for. On this basis, then, we may speak of macular leprosy, tubercular leprosy, bullous leprosy, pigmentary leprosy, nodose leprosy, scaling leprosy, ulcerative leprosy; and as aberrant occurrences, atrophic leprosy, mutilating leprosy and papular leprosy.

MACULAR LEPROSY

Macular leprosy may occur in three forms. First, as an expression of a general impression of the individual carrying a circulating infection of the disease and its organism. Such an eruption is evanescent; it has all the characteristics of an erythema multiforme of toxic type and the eruption is not characteristic of leprosy. Here the lesions are of various sizes, bilateral and symmetric, general over the whole body, and are light red, level with the skin, fade on pressure, have no fixed pigment and may be quite hyperesthetic so far as itching, heat and hypersensibility are concerned. Such macules may disappear entirely or they may continue *in situ*, giving gradual place to infiltrated and even nodose lesions in the same areas. More often they disappear and may recur months afterward. With such evidences the general symptoms of leprosy are associated.

Macular leprosy may be pigmentary from the start. Over the buttocks, hands, face and legs, particularly, the eruption shows in reddish-brown macules, more or less rounded in outline, level with the skin, and persistent in all of these characteristics.

The true type of macular leprosy is the most characteristic. Ovoid macules, varying in size, appear on the face, over the shoulders, over the arms and forearms, over the legs, more or less scattered, edges elevated and centers depressed; often the edges are highly pigmented, brown or purplish, and the center is of normal color or even a dirty white.

The last-named macules are anesthetic; the others are not. The anesthesia is more marked at the borders. More than this, in the borders of the last-named macules, it is usually easy to demonstrate the lepra bacilli; in the first two varieties of macules, it is almost impossible to find any bacilli—arguing, as has been suggested, that the eruption is rather an exanthem than a deposit.

Macular leprosy must be differentiated from syphilis, and from erythema multiforme. From the first the macules may be easily distinguished by their preference for the extensor surfaces, by their large size and by the peculiar dusky color in the pigmentary forms. Macular syphilis is not infiltrated.

From erythema multiforme, the diagnosis is made on the more established eruption, lasting weeks or months, and in the pigmentary and infiltrated types by the fact that in both the lesions do not fade on pressure. Sometimes iodism produces infiltrated lesions resembling leprosy, but here the whole lesion is turgescent and highly inflamed, and therefore red and not dusky-brown red.

TUBERCULAR LEPROSY

The tubercle of leprosy is of two forms.

The large tubercle is found about the nose, on the chin, cheeks, in the pendulous portion of the ear and sometimes on the hands and on the legs. The color of these lesions is characteristic—brown red. They are firm, rounded masses, deep set in the skin, not uniform in size and with no tendency to disintegrate while the general condition of the patient is good. The lesions are almost invariably anesthetic.

Lupus and syphilis may be confused with this form of tubercle. In lupus the lesion is purple, granulomatous in consistency and ulcerating as soon as the tubercle is mature. The general symptoms in leprosy (nasopharyngeal and laryngeal, particularly) are ordinarily concomitant. In syphilis the tubercles are smaller, grouped in crescentic formation, and scar in ulcerating, with marked and characteristic pigmentation.

The small tubercle of leprosy is quite different. Here the lesions cluster close, like small pea-sized bits of beeswax embedded in the skin. Over the backs of the hands, the chin, the borders of the lips and the cheeks are the sites of predilection. The lesions are a dirty yellow. This type of tubercular leprosy is usually rapid in its course, presumptively because the lesions in the skin are probably only the expression of a general tubercular condition of the viscera. These lesions are likewise anesthetic.

Only xanthoma and disseminate tuberculosis need to be considered in differentiation. Xanthoma presents flat tubercles, deep seated, bright yellow, smooth and usually lissom to the touch. Stretching the skin in xanthoma shows the streaks of connective tissue in the striae of the lesion; stretching the skin in leprosy only intensifies the waxy appearance of the tubercle. Xanthoma at times is painful; leprosy is anesthetic.

Tuberculosis of the miliary form may be disseminate in the skin and may be found in the areas in which tubercular leprosy is found. The lesions are in closer formation; usually occur as smaller tubercles and usually are found about the joints rather than at the peripheral extremities. Confusion often arises in these two conditions occurring on the face, but as the organisms of leprosy and of tuberculosis can be almost always demonstrated, this method, even carried to cultural procedure, will finally decide.

BULLOUS LEPROSY

Bullous leprosy must be noted as important, particularly as it is an early form. The lesions come on the hands or feet, over the joints of the fingers, as a rule. The bullae repeatedly occur at the same spot, until finally the epidermis is lost and bullae can not form. Scarring, with mottling pigment, follows. Sometimes, necrosis supervenes and the deformity from loss of bones may result. This dermatologic evidence is really the expression of a disturbance in the nerve, usually the ulnar, along which may be found, when the bullae occur, marked thickening or even distinct nodosities along the sheath. But I am limited to cutaneous leprosy, so may not further digress.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-fourth Annual Session, held at Minneapolis, June, 1913.

PIGMENTARY LEPROSY

In some instances the local evidence of leprosy manifests itself in diffuse pigmentation of the face, neck, trunk, hands, arms and legs. At times the whole body may be so pigmented. The slight mottling is peculiar to this disease and makes the differentiation from the pigmentary evidences in vitiligo (in which the demarcation of color is abrupt), in Addison's disease (in which the pigment is solid and in selective areas), in syphilis (in which the mottling is limited to the neck) and in mycosis fungoides (in which the pigment is always cast over or under the premycotic furfuraceous scales).

NODOSE LEPROSY

Nodose leprosy is usually facial, coming on after the diffuse macular form has spread over the face and has persisted. As the skin thickens, rugosities develop and each of these separate into larger or smaller masses, forming nodes. At first there is some mobility, but this gradually disappears until a true satyriasis is established in the facies; and as the disease grows older and the skin roughens, there grows a more and more fixed condition of the skin, until the rugae resemble the thickened areas so characteristic of the lion's face and from which has been derived the term "leontiasis" as applied to this form of leprosy. Ulcers now ensue as a result of failure in nutrition, and one by one the features change by necrosis until the last stage of a fearful process may end the history of the case by death.

Hypertrophic rosacea, when general over the face, may resemble leontiasic leprosy, but at no time is the mobility lost, and the skin remains soft in spite of hypertrophy.

Chronic edema may likewise be mistaken for this disease, but in edema the smooth skin with the pitting over all areas makes a clear diagnosis, even if the complication of the keratinous changes in the eys, and the ulcerative changes in the respiratory tract were not also in evidence to proclaim a more sinister diagnosis.

SCALING LEPROSY

Scaling leprosy is rare. Here the whole skin shows signs of degenerative change, and wrinkling is seen everywhere. No part of the body is free. Thinning instead of thickening occurs, and it is not hard to find the trophic changes of the skin accompanied by like changes in the peripheral nerves and in the mucous membranes of the nasopharynx. The conjunctivae are also involved and ectropion is common. The musculatory changes in the hands are also present and the peripheral nerve changes are found at the same time as the general scaling of the body. The skin everywhere has a dirty gray color, with lines of atrophy showing through the scales. The loss of hair over the pubis, in the axillae, over the body and of the eyebrows, lashes, beard and scalp carry further the picture of the atrophic process.

Xerosis in all its forms is easily differentiated by the consistent atrophy in the leprosy of this form. In xerosis the process is as consistently hypertrophic and the more severe the scaling in xerosis the more the tendency is to hypertrophic change.

ULCERATIVE LEPROSY

Ulcerative leprosy is nearly always found as an expression of nerve destruction and located on the sole of the foot, usually under the fleshy part of the great toe; it may occur at the heel. This ulcer, "neurotic ulcer" in type, is usually one of many symptoms of nerve leprosy, but as an ulcer it shows cutaneous evidence and must be mentioned here. The cylindrical cavity, sharply outlined, rather deep, and the hard and horny edges, with the nauseating odor, are sufficient to make a diagnosis.

ATROPHIC LEPROSY

Atrophic leprosy is also of nerve origin, but with cutaneous expression usualy referred to the extremities. The whitlow, atrophy of the skin of the hands and feet, loss of intermediate phalanges resulting in superficial ulcers and in deformity, the scarring and pigmentation, all are the cutaneous evidences. Syringomyelia may be of other than leprous origin, but the altered or lost sensation, associated with peripheral lesions like the foregoing, the occurrence of contractures of the hand, of atrophy and of occasional bullae, should lead to a search for the bacilli for a differentiation.

When leprosy is advanced, all lesions may give way to degenerative changes, and tubercles or macules may break down, so that ulcerative leprosy may become general. The nasal bones break down; the lips excoriate and slough off; fingers drop; toes are spontaneously amputated; the legs or arms show areas of necrosis, and finally the terminal members one by one are made to fall until at last "the frame bears only semblance of its past, human once, but now distorted, bound in shapes fantastic and shorn of everything but form."

PAPULAR LEPROSY

In the various exacerbations of leprosy, particularly when the lesions begin to break down, when the toxins are liberated, or the masses of dead bacilli are sent into the circulation, there is frequently a rise of temperature, producing the "fever of leprosy," now recognized as an entity. With this process a general eruption appears of lenticular papules. This is the only form of papular leprosy so far known, and it is questionable if it may be properly called papular leprosy, as the papule is really only an evanescent exanthem, disappearing with the defervescence of the attack.

The papules are free of organisms and are purely exudative in type, inflammatory and hyperesthetic if the sensation is disturbed at all.

CONCLUSION

Much more might be said of cutaneous leprosy, but in the time allowed in a symposium of this sort it would be impossible to handle the subject exhaustively. The final word may be said that by learning the lesions which may be present in leprosy, it may be possible to recognize them by differentiation, while the attempt to carry pictures of classical descriptions may fail of service in the simple cases in which a diagnosis means so much in the matter of care and cure.

124 Baronne Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. DYER, BOECKMANN AND BLUE

Dr. H. M. Bracken, St. Paul: My chief interest is in the care of those afflicted with leprosy. Those who have to do with the handling of this disease appreciate the importance of an early diagnosis. It was said in the past that we had no American-born lepers in Minnesota. We now have a record of seven lepers born in Minnesota, four of whom are still alive. When a resident of this state becomes infected with leprosy we can attribute it to one of two causes, either a failure to diagnose the disease sufficiently early in those who are exposing others, or an unsanitary condition in the family that makes it almost impossible to prevent infection. This disease is not contracted casually; it is not picked up in the railway-cars or in the street-cars; it is a house disease. From the administrative point of view it should be easier to control this disease than tuberculosis, and yet people have the greatest dread of leprosy and practically pay little or no attention to tuberculosis. This is not reasonable. In 1900 I collected data covering twenty-seven cases in living patients in Minnesota; now we have but thirteen. From this it can be seen that the disease is gradually disappearing. All of the cases in Minnesota, except the seven already referred to, have been brought in from other countries. Many of the early cases were brought in from Norway and Sweden, but latterly from other countries, namely, Italy, Canada, the Philippine Islands, etc.

The important question is, How are we going to take care of the lepers? Dr. Blue's paper dwelt on this phase of the subject. It is not practicable for each state to maintain a leprosery. There are not enough cases to demand it. The troubles in Texas emphasize this difficulty. In this state, as a rule, we have been able to handle the cases at home. Many of the lepers are in comfortable circumstances, and when they are reported to us we simply tell them the danger to the other members of the family and recommend that proper precautions be taken to prevent infecting others. These recommendations they will gladly carry out, as a rule, for they do not want to infect their own people.

The national government should provide a leprosery; but where? Whenever this question is raised, as Dr. Blue states in his paper, a local sentiment is worked up against it. We might, of course, try to get some of those states which have made provision for the care of lepers to open the doors of their institutions to lepers from other states, on a business basis.

Dr. M. L. Graves, Galveston, Tex.: Texas has lepers. As a matter of fact, the law and appropriation had its origin in Galveston, where the larger number of leprosy cases have occurred in the state. A few years ago Dr. E. S. Cox, our county physician, collected statistics showing that about fifteen lepers had been living in Galveston at various times. Our health physician then went before the state legislature and presented photographs of the quarters of these lepers and of their distressing conditions and secured an appropriation of forty thousand dollars to erect a lepers' home. A commission was appointed by the governor, and traveled over the state of Texas, uninvited and frequently repelled by communities, until it had to give up in disgust the opportunity to establish this home.

During the eight years in which I have been in Galveston, there has hardly been a year in which I have not been able to demonstrate to my classes cases of leprosy. We have no means or methods of isolation, legally, in our state. The first case that I exhibited to my classes was that of a negro. When I saw that patient two years later at Houston, I found him in the suburbs sitting on the platform of a suburban saloon, surrounded by fifteen or twenty laborers. On account of the wide distribution of the disease throughout the United States, and the indisposition of local communities to care for these patients—the work is nowhere well done, so far as I know, except, perhaps, in the state of Louisiana, under the direction of Dr. Dyer—it seems to me that it would be best for us to endorse the recommendation of Dr. Blue and establish a federal leprosarium to take care of these people. I believe that it will be far easier to do something of that kind when we have a national department of health with a cabinet officer at its head.

Dr. Guilford H. Sumner, Des Moines, Iowa: I wish to lend my influence and my hearty approval for the establishment of a leprosery whereby the states may be relieved in cases of emergency. One evening I received a telegram from the secretary of the State Board of Health of Michigan, stating that a leper had escaped from that state and was probably located in the city of Centerville, Iowa. I immediately telegraphed a member of our board who lives at Centerville, and by 10 o'clock that night he had the man located. He had been a resident of the state of Michigan for about twenty-eight years. I was assured by the Michigan board that the state of Michigan would remove him, and I at once placed him under quarantine, as provided for in the Iowa rules and regulations, and expected, of course, that he would be removed by our sister state. Days and weeks passed, and finally I was notified by the Michigan secretary that they had no money to remove this patient, but that if we would send him home they would receive him. I at once began to take steps to return this man to Michigan, and I at that time did not consider it a very serious proposition, but, after communicating with Surgeon-General Blue, I found that I would have to remove him in a special car and send an attendant. The railway company said that they would remove the leper for eighteen fares from Centerville, Iowa, to Chicago, and for twenty-five fares from Chicago to Bay City, Mich. I inquired the cost and was told that it would be $216. Just as I was about to make arrangements to move him, the railway company told me that they had concluded that they would have to remove him by special engine and car. I again inquired the cost and was told seventy-five fares from Centerville to Chicago, and one hundred fares from Chicago to Bay City. I asked the cost and was told $1,160. I appealed to the governor and the executive council of my state to ascertain what I could do. I was told that there was no money with which to remove the leper. By that time all were anxious to have the leper removed from the state. I was at a loss to know what to do. The next obstacle was that the secretary of the Michigan Board of Health had served notice on the Michigan Central Railroad that no car or train bearing the leper would be permitted to enter the state of Michigan or stop at Bay City. The governor and executive council gave me five hundred dollars to pay expenses of moving. I employed a fellow with a big touring-car and gave him the five hundred dollars to convey the leper across Indiana and Illinois and into the state of Michigan. I obtained the consent of the Illinois board and the Indiana board. The car was fumigated and disinfected and brought back to Iowa, and my trouble ceased.

Now I do not know that this will occur again, but with a leprosery under government control I think that we might be able to turn our lepers over to the U. S. Public Health Service.

Dr. W. C. Rucker, Washington, D. C.: Very few of the national governments of Europe have any national quarantine system. If a leper went to England, the vessel would be met by the officials of the customs service, who would look over the passengers on the boat, and then notify the port physician if they discovered any disease which they considered quarantinable. He would then come and look over the suspected persons; but the preliminary diagnosis is made by a non-medical man. France has a quarantine system, but it is not a national quarantine system; it is governed by the various departments of the French government. There is no national quarantine system in Germany. I think there are four states of the twenty-six which have a quarantine and each one has its own independent system. They operate entirely independently, as a rule, but occasionally unite in important instances. I do not know what the Italian and Spanish quarantine systems are, but I do not think that they are very extensive. The United States is the only country in the world that has established a good and complete national quarantine system.

Dr. E. Boeckmann, St. Paul: When I was in Bergen I was instrumental in exporting some lepers to Minnesota, because it was the general belief that when they came over here they would do much better and not be a menace to the population, and I think that that has proved true. On the other hand, I have been instrumental in sending lepers back again, on account of my influence with Dr. Danielsen at the hospital in Bergen. I wrote him asking if he would be kind enough to receive lepers from here on three or four occasions in the earlier days of my residence in Minnesota. They went out without any trouble whatsoever. I am positive that, if a Norwegian here in Minnesota has become a leper after coming to this country, the authorities in Norway would be willing to take him back again to one of their national leproseries, if transportation could be arranged for.

MORBIDITY REPORTS

THEIR PURPOSE AND PRESENT STATUS [*]

JOHN W. TRASK, M.D.
Assistant Surgeon-General, United States Public Health Service
WASHINGTON, D. C.

As knowledge has been acquired of the causes of disease, and it has become known that a large number of diseases are preventable, communities have established health departments. The health department as it is now understood is a comparatively modern institution. Its era may be said to have just begun.

THE PURPOSE OF MORBIDITY REPORTS

Whenever a community or state has progressed in its social life to the point where it has established an active health department it has required that physicians report the cases of certain diseases occurring among their patients. This has been recognized as a necessity, for the work of the health department is, if anything, the prevention of disease; and no health officer, no matter how efficient he may be, or how many able assistants he may have, can hope effectively to prevent or control a disease in a community unless he has some means of knowing when, where and under what conditions cases of the disease are occurring. Aside from any influence he may have in securing unpolluted water-supplies and better living and working conditions for the people generally, his field of action is practically limited to the notifiable diseases, and the extent and effectiveness of his work are determined by the completeness with which cases are reported by physicians. Unless cases are reported the health officer is in the position of one trying to combat an invisible enemy of whose location, numerical strength and times of attack he has no knowledge.

Morbidity reports had their origin in the requirement that cases of certain especially dangerous contagious diseases be notified to the proper authorities. This was for the purpose of making known the foci of these diseases so that the well could avoid unnecessary exposure, and, in some instances, so that the authorities could institute measures to prevent further dissemination of the infection. As knowledge of the means of spread of the communicable diseases has been acquired, the importance of knowing of the occurrence and location of cases has become more and more apparent. With increasing information of the preventability of many diseases and the possibility and need of their control, there is a proper tendency to require the notification by practicing physicians of cases of not only the more dangerous contagious maladies, but also of other infectious diseases, and of some diseases which are not known to be infectious, as cancer and pellagra. The last two named and others of their kind have been made notifiable because of the importance of knowing of their occurrence and varying prevalence, and the possible value of such knowledge in assisting in the finding of their causes and means of spread. In the case of at least one disease, ophthalmia neonatorum, notification has been required of nurses, midwives and parents for the purpose of making prompt and efficient treatment possible.

Recently a number of states have passed laws requiring the notification of certain industrial diseases, chief of which are the metallic poisonings. This is primarily for the purpose of showing where conditions exist capable of producing these affections so that measures may be taken looking to the remedying of the conditions and the prevention of similar injury to others.

The present purpose of morbidity reports is primarily fourfold and may be stated as follows:

1. To show the occurrence of cases of infectious diseases which constitute foci from which the infection may spread to others, as in scarlet fever, tuberculosis and small-pox.
2. To show the occurrence, distribution and varying prevalence of certain maladies of which the cause or means of spread is unknown, because of the possible value of this information in ascertaining the cause or means of spread, as in pellagra and cancer.
3. To make proper treatment possible, as in ophthalmia neonatorum.
4. To show the existence and location of conditions that are capable of causing illness or injury, as in the industrial diseases.

MORBIDITY REPORTS IN ENGLAND

In England beginning with the year 1911 the medical officer of the local government board has compiled reports of the notifiable diseases for all England and Wales. These diseases are small-pox, typhus fever, scarlet fever, diphtheria, typhoid fever, puerperal fever, erysipelas, plague, cholera, relapsing fever, pulmonary tuberculosis (added Jan. 1, 1912), cerebrospinal fever (added Sept. 1, 1912) and acute poliomyelitis (added Sept. 1, 1912). The local sanitary officers are required by a general order of the local government board, promulgated Dec. 13, 1910, to transmit to the medical officer of the board each Monday a statement of the cases notified to them during the preceding week. The medical officer of the local government board is the chief sanitary officer for England.

The experience leading to the present system for morbidity reports in England and Wales was similar to that through which the United States is now passing. Soon after the establishment of the registration of deaths in England, in 1837, it became evident that the record of deaths did not give the kind of information necessary for the control of disease and that sanitary officials must have other and additional knowledge of the occurrence of cases. Various men, societies and associations advocated at different times plans for the notification of sickness throughout the country. The British Medical Association, as far back as 1865, made repeated efforts to have adopted a uniform system for morbidity reports.

MORBIDITY REPORTS IN RUSSIA

In Russia sanitary regulations adopted in 1905 require that all physicians, whether engaged in private practice or in government service, shall forward to the local sanitary inspector having jurisdiction a monthly report of patients treated by them in private practice and in hospitals, the reports for the patients in private practice and those in hospitals to be made separately. In addition to this every case of infectious disease is to be reported at once. A heavy penalty is imposed for those failing so to report. Every hospital and clinic is also required to keep a detailed record of its patients and report regularly to the sanitary inspectors. The data received by the local sanitary officials in the monthly reports from hospitals and practitioners are compiled and forwarded annually to the chief sanitary inspector of the Ministry of the Interior on forms printed for the purpose. The chief sanitary inspector at St. Petersburg compiles these reports of the occurrence of sickness throughout the empire and publishes them annually.

---

[*] Read in the Section on Preventive Medicine and Public Health of the American Medical Association, at the Sixty-Fourth Annual Session held at Minneapolis, June, 1913.

[*] Because of lack of space, this article is abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints.

These sickness records for Russia include all parts of the empire. Among the infectious diseases for which statistics of the occurrence of cases are compiled are small-pox, scarlet fever, diphtheria, measles, whooping-cough, influenza, typhus fever, typhoid fever, dysentery, cholera nostras, Asiatic cholera, epidemic gastroenteritis, mumps, erysipelas, septicemia and pyemia, rheumatic fever, croupous pneumonia, tuberculosis, malaria, scabies, trachoma, syphilis, soft chancre and gonorrhea. Statistics are also compiled for mental diseases, traumatic affections and vaccination for small-pox.

MORBIDITY REPORTS IN THE UNITED STATES

In the United States the requiring of the notification of cases of sickness is a power residing in the respective state legislatures. In some of the states authority has been given to the state boards of health to cover the subject by regulations. In most instances local authorities have the right to supplement the state requirements by such additional ones as may be needed. The laws and regulations of the several states differ widely, as do also the efforts made to enforce them.

The common and most general plan is to require that the original report be made by the physician to the local health officer immediately on diagnosis of the case. The local health officer, either immediately or at intervals, forwards to the state health department a transcript or a summary of the notifications received by him. In a number of states these reports by the local health departments are made to the state authorities daily, in some weekly, in one state (Ohio) twice a month, in several states monthly, and in a few states at longer intervals. In the states in which the reports are made daily the state health department is in a position to keep constantly informed regarding the prevalence of the notifiable diseases. The same is in less measure true when the reports are made weekly. When the reports are made at longer intervals the current value of the information to the state department is largely lost.

In one state (Florida) physicians are required to report the notifiable diseases directly to the state health officer or his representative, the commoner diseases by mail, and yellow fever, small-pox and cholera by telegraph at state expense. This in effect makes the state health officer also the local health officer and responsible for the control of the notifiable diseases, the control of disease and the notification of cases being inseparable, the latter giving the necessary information by which to direct action in the former.

In the states giving special attention to the control of disease the territory has been so divided that all parts are within the jurisdiction of a local health department responsible for the notification and record of sickness and sanitary administration in matters strictly local in nature. In most instances the cities have their own health departments, and rural territory is under the jurisdiction of either county or township health officers.

So far as the results obtained are concerned the effectiveness of public health administration depends not so much on the nature and extent of the state laws and regulations as on the manner and degree of their enforcement. This is true of the requirements for morbidity reports as well as those relating to other subjects. State laws regarding the notification of disease and most other public health matters are impossible of proper enforcement unless the state health department has some control over local health officers. When the local health authorities are responsible only to their respective communities the state health department is practically without jurisdiction, and its usefulness is limited. In South Dakota this control over local authorities is obtained by making the county board of health consist of the state's attorney for the county and two physicians appointed by the state board of health; one of these physicians becomes the county superintendent of health. In Indiana the state board of health has the power to remove from office any county health commissioner or health officer in the state. In Virginia the state board of health appoints three physicians in each county and city who, with the chairman of the county supervisors or the mayor of the city, constitute the county or city board of health. In most states the local boards of health or health officers are either elected or appointed locally and the state has little if any direct control over their work. Still other plans have been adopted in other states.

THE NOTIFIABLE DISEASES

The following-named diseases are those specified by the various state requirements with the number of states in which each is notifiable:

Actinomycosis	2
Anthrax	7

Anthrax	6
Compressed-air illness	7

Forty-eight different diseases are specifically named as notifiable by law or regulation in one or more states. These are in addition to industrial diseases and mental deficiency. Fourteen diseases, cerebrospinal meningitis, cholera, diphtheria, leprosy, measles, plague, poliomyelitis, scarlet fever, small-pox, tuberculosis, typhoid fever, typhus fever, whooping-cough and yellow fever, are notifiable in twenty or more states. Small-pox is specifically made notifiable in forty-four states. This is a greater number than that for any other disease. Diphtheria is notifiable in forty states and scarlet fever in thirty-nine. Of the less commonly notifiable diseases cancer is notifiable in New York State and Chagres fever in Alabama. Venereal diseases are notifiable in California, Utah and Vermont. When reported, however, the name of the patient need not be given. In Porto Rico syphilis is among the notifiable diseases. Cases of mental deficiency, including epilepsy, are notifiable in New Jersey. Amebic dysentery and paratyphoid fever are notifiable in the state of Washington and the territory of Hawaii; barber's itch is notifiable in Oregon; favus, echinococcus disease and paragonimiasis are notifiable in Washington and follicular conjunctivitis in Hawaii.

Occupational Diseases.—Eight states have enacted laws requiring the notification by physicians of certain occupational diseases. These states are California, Connecticut, Illinois, Maryland, Michigan, New Jersey, New York and Wisconsin. The diseases specified in seven of the laws are compressed-air illness and poisoning by lead, phosphorus, arsenic or mercury or any of their compounds. Anthrax is named in six of the laws. The Illinois law, which differs to some extent from the others, requires that employers engaged in carrying on any process of manufacture or labor in which sugar of lead, white lead, lead chromate, litharge, red lead, arsenate of lead or Paris green are used, or in the manufacture of brass or the smelting of lead or zinc, shall once every calendar month have all the employees who come into direct contact with the poisonous agencies or injurious processes examined by a competent physician to ascertain if there exists any occupational disease. The physicians who make these examinations are to report their findings immediately to the state board of health. In six of the states the physicians report to the state board of health, in Connecticut to the commissioner of the Bureau of Labor Statistics and in New York to the commissioner of labor.

RESULTS ATTAINED IN CERTAIN STATES AND CITIES

The completeness of the reports of the notifiable diseases in states and cities in which there is registration of deaths may be estimated with some degree of accuracy by comparing the number of cases reported with the number of deaths registered as due to the same cause. In doing this, however, it must be borne in mind that we do not know the fatality-rate of many diseases, for up to the present there have seldom been satisfactory morbidity records of sufficiently broad application to permit of the determination of such rates, and also that the fatality-rates of many diseases vary from year to year and with the seasons and geographic locations.

Typhoid fever.—To show the results obtained in the notification of typhoid fever five states and three cities have been taken, all of which publish their morbidity records.

TABLE 1.—NUMBER OF CASES OF TYPHOID FEVER REPORTED FOR EACH DEATH REGISTERED*

States	1906	1907	1908	1909	1910	1911	Aver.
Colorado	7.2	7.6	7.9	7.3	7.3	...	7.46
Connecticut	4.4	5.0	6.2	5.8	6.6	...	5.6
Massachusetts	6.3	5.9	7.2	7.0	...	...	6.6
Michigan	4.1	3.0	3.6	3.9	4.9	...	4.9
New York	...	...	5.0	6.0	6.2	...	5.44
Cities							
Boston	8.1	9.0	10.0	7.3	8.1	7.9	8.4
New York	5.4	6.0	5.7	6.2	6.4	6.3	6.0
Washington, D. C.	6.9	8.1	7.5	6.8	8.8	...	7.62
Hospitals							
Boston City	...	...	...	7.6	7.0	9.3	7.96

*In this table and Tables 2, 3 and 4, the years ended Jan. 31, 1910, 1911 and 1912.

Among the states the highest average was 7.46 in Colorado and the lowest 4.9 in Michigan. Among the cities the highest average was 8.4 in Boston. This was higher than that for the city of Washington, although during the period under consideration typhoid fever was under special investigation there and the morbidity records were presumably reasonably complete. It will be noted that the average number of cases reported for each death was higher in the states of Colorado and Massachusetts as a whole than in the city of New York. The greatest number of cases per death reported for any one year in the states and cities enumerated was ten in Boston during 1908; the lowest was three in Michigan during 1907. It is of interest to compare with these averages that of the Boston City Hospital, in which during the three years 1909 to 1911 there was an annual average of one death in every 7.96 cases.

The averages for the same years were not taken in all instances, as the annual reports for recent years were not yet available for some of the states and cities.

Diphtheria.—Averages for diphtheria similar to those given for typhoid fever appear in Table 2.

TABLE 2.—NUMBER OF CASES OF DIPHTHERIA REPORTED FOR EACH DEATH REGISTERED

States	1906	1907	1908	1909	1910	1911	Aver.
Colorado	5.6	5.2	6.6	9.3	8.3	....	7.0
Connecticut	6.8	7.5	7.8	9.5	8.8	....	8.08
Massachusetts	11.2	11.9	12.0	10.8	....	....	11.47
Michigan	8.1	7.5	7.7	7.7	7.5	....	7.7
New York	....	....	8.6	8.9	9.3	....	8.9
Cities							
Boston	....	16.4	15.6	13.7	15.5	17.0	15.64
New York	....	8.8	9.3	8.9	9.9	10.5	9.48
Washington	....	14.7	21.9	12.3	15.3	....	16.05
Hospitals							
Boston City	....	....	....	11.7	15.3	12.8	13.27

It will be noted that the highest average number of cases reported in the three cities was 16.05 in Washington, and the highest average for the states 11.47 in Massachusetts; also that the Massachusetts state average is a trifle higher than that of New York City, and that the averages for both Boston and Washington are higher than that of the Boston City Hospital.

Scarlet Fever.—Similar averages for scarlet fever are given in Table 3.

TABLE 3.—NUMBER OF CASES OF SCARLET FEVER REPORTED FOR EACH DEATH REGISTERED

States	1906	1907	1908	1909	1910	1911	Aver.
Colorado	17.0	14.4	14.3	11.3	18.6	....	15.12
Connecticut	28.8	20.9	27.2	19.1	24.3	....	24.06
Massachusetts	38.7	27.8	20.6	25.2	....	....	28.07
Michigan	12.0	15.1	16.0	18.1	21.5	....	16.54
New York	....	....	18.2	18.4	19.5	....	18.7
Cities							
Boston	34.4	48.1	25.9	21.4	35.3	20.7	30.97
New York	....	19.8	18.3	15.8	19.8	21.3	19.0
Washington	28.9	84.0	32.7	34.8	91.0	....	54.28
Hospitals							
Boston City	....	....	....	19.6	22.7	18.6	20.3

In the states given, the highest average number of cases reported for each death was 28.07 in Massachusetts, and the lowest 15.12 in Colorado. In the cities the highest average was 54.28 in Washington. The Boston City Hospital average was 20.3 and was exceeded by that of the states of Connecticut and Massachusetts and the cities of Boston and Washington. The large annual average number of cases, 54.28, reported in the latter city for each death may possibly be due to a difference in the virulence of the disease.

Measles.—Similar figures for measles are given in Table 4.

TABLE 4.—NUMBER OF CASES OF MEASLES REPORTED FOR EACH DEATH REGISTERED

States	1906	1907	1908	1909	1910	1911	Aver.
Connecticut	29.3	30.5	34.4	55.1	43.7	....	38.6
Massachusetts...	74.8	39.8	44.2	58.6	....	....	54.35
Michigan	39.4	48.2	40.1	34.1	58.8	....	44.12
New York	....	....	50.9	40.6	54.4	....	48.63
Cities							
Boston	79.3	46.4	39.0	37.8	42.5	57.4	50.4
New York	....	22.8	39.4	34.0	45.1	38.8	36.02
Richmond	....	35.0	51.1	40.0	80.4	....	51.62
Washington	....	....	589.0	170.1	80.3	....	279.8
Hospitals							
Boston City	....	....	....	8.3	18.1	19.3	15.23

The highest state average for measles was that of Massachusetts, 54.35 cases; the highest city average was 279.8, that of Washington, where in 1908 there were 589 cases reported for each death. The lowest state average, 38.6, that of Connecticut, was higher than the lowest city average, 36.02, that of New York City, and over twice as high as the average in the Boston City Hospital. In the table for measles the City of Richmond, Va., was added because during the year 1910 special attention had been given by the health department to the notification and control of the disease. During that year, as will be noted, there were over eighty cases reported in the city for each death. As in scarlet fever in the city of Washington, whether the large number of cases reported for each death was due to a better reporting of cases or to a less accurate registration of the causes of death or to a diminished virulence of the disease is a matter of conjecture. The comparatively high fatality-rate of the Boston City Hospital is in accord with the common experience of hospitals, which undoubtedly accounts for the comparatively high fatality-rates usually cited in medical literature.

In this connection recent epidemics of measles in a number of cities are of interest. During epidemics the wide-spread prevalence of the disease is common knowledge, and it may properly be expected that at such times the notification of cases will be unusually complete.

The cases and deaths reported in these outbreaks are shown in Table 5.

TABLE 5.—CASES AND DEATHS REPORTED IN RECENT EPIDEMICS

	Cases	Deaths	Number of Cases for Each Death
Pittsburgh, Pa., 11/1/12 to 5/10/13 ..	9,003	147	61.2
St. Louis, 4/1/12 to 2/28/13	4,281	37	115.7
Richmond, Va., 1/21/13 to 4/26/13 ...	3,821	22	173.2

CONCLUSION

As the control of disease presupposes a knowledge of its occurrence, it is of importance that every local health officer know of the prevalence of disease not only in his own jurisdiction but in neighboring cities and counties as well. In the United States the state health department needs to know of the prevalence of disease throughout all parts of its territory, and also in neighboring states. For the purpose of the more extensive and more efficient public health work which is much desired there is needed a carefully worked out plan whereby all health authorities can be advised currently of the existence of epidemics and the prevalence of disease throughout the country. In addition to the information this would give of the approach of extending epidemic diseases, it would add immeasurably to our knowledge of epidemiology. Such a plan depends first on the conscientious reporting of cases by the physician to the local health authority, and secondly on prompt reporting by the local authorities to the state health department. The scheme, however, is not complete without the reporting by the state authorities to some common agent that will serve as a clearing-house for the state reports and publish the data at frequent intervals for the information of all. The latter is now being done in so far as it is possible. Practically all the states in which attempts are being made to secure exact knowledge of the current prevalence of disease by morbidity reports report to the Public Health Service the occurrence of disease in their respective states. For the immediate information of all the states provision has also been made for telegraphic reports at government expense of the occurrence of epidemics and of cases of diseases especially dangerous. This provision is for telegraphic reports by the state authorities to the Public Health Service of the occurrence of epidemic diseases in their respective jurisdictions. It also provides for the telegraphing by the Surgeon-General of the Public Health Service of the information thus received to the state authorities to whom the knowledge may be of value.

Pursuant to acts of Congress the reports of the occurrence and prevalence of disease received from state authorities and from other sources are published in the *Public Health Reports* of the Public Health Service, which are sent to state and local health authorities and to other sanitarians. These reports are issued weekly in editions of 8,000 copies and show among other things the current prevalence of disease throughout the United States, in so far as the information is available, and the prevalence of certain of the more dangerous epidemic diseases throughout the world.

300 R Street N.-E.

ABSTRACT OF DISCUSSION

Dr. Pauline M. Townsend-Hanson, Marshalltown, Iowa: I believe that Iowa in the last legislative session passed a law making venereal diseases reportable.

Dr. P. M. Hall, Minneapolis: Minnesota at the last legislative session made occupational diseases reportable.

Dr. James A. Hayne, Columbia, S. C.: The point in Dr. Trask's paper, outside of statistics, that interests me most, is that we need a clearing-house for our morbidity reports from the different states; that is, when a disease is epidemic in some of these states, or a focus of an epidemic has started in a state, health officers of other states should know something about it. This was brought to my mind the other day by the fact that I had a relative who wished to go out to Texas; when she went to buy a ticket, she found that Texarkana was quarantined on account of a cerebrospinal meningitis epidemic. I, a health officer, did not know that there was cerebrospinal meningitis in that place. Health officers should know these things, so as to be able to prevent the spread of disease from one state to another.

The Public Health Reports being printed weekly by the U. S. Public Health Service should show when such foci exist, but a great many states in the Union make no morbidity reports whatsoever. South Carolina does make morbidity reports. They are not accurate, but, still, they show when there is a focus of infectious disease in any county. We make these reports monthly to the U. S. Public Health Service by whom they are sent out, and the people of Georgia, or North Carolina, or in other neighboring states, are able to see that such diseases are present in our state.

For instance, we have had about two thousand cases of small-pox in the last two years; we have had probably about 1,100 cases of measles since Jan. 1, 1913. None of the so-called registration area states report anything like that number. We have also had cerebrospinal meningitis. We should have better reports of morbidity statistics made to a central office.

Dr. Liston H. Montgomery, Chicago: I can conceive of a case in which an adult contracts scarlet fever and the malady is so diagnosed by a reputable physician. For obvious reasons, he is dismissed from the case. Another equally reputable physician is called and fails to confirm the diagnosis. In the course of a few days, children in that family may become ill with scarlet fever and the second physician treats those children for scarlet fever. The question is, did the first person in that family, the adult person, have scarlet fever, or not? No other source of contagion was traced.

POSTOPERATIVE RENAL INFECTION *

HENRY DAWSON FURNISS, M.D.
NEW YORK

Postoperative renal infection may occur from an infection in some other part of the urinary tract, or be first in the uropoietic system. Already existing infections of the kidney pelvis may be the source of infection for infection of the renal parenchyma.

Independent of operation, renal infections occur during typhoid, attacks of tonsillitis, furunculosis, or from carbuncles and paronychiae. While any one of these causes may exist after operation and be the real etiologic factor of the renal infection, only such infections as occur as a direct result of the operation or its complications are here considered.

Baisch[1] states that in healthy women the urethra is seldom the seat of pathogenic bacteria, but that in those post partum, and after operation, the urethra becomes the habitat of infectious micro-organisms, and that the number present is in direct ratio to the length of time that the woman remains in bed. To this might be added that in the cases post partum and in operation attended with a discharge that bathes the urethra, the organisms are more plentiful. Such bacteria are then introduced into the bladder by catheterization, no matter what care is taken to cleanse the external genitals, and in a bladder already injured and not able to empty itself, cystitis is very apt to take place. This is especially frequent in patients operated on radically for carcinoma uteri.

A. Bauersein[2] found in eighteen autopsies following operation for carcinoma, cystitis in all, but no evidence of the infection extending through the bladder wall. He regarded the granulation tissue as a barrier to such extension, and found no bacteria beyond this. He considered the bladder infection as being due to introduction of infectious material through the urethra, or due to infection passing downward from the hematogenously infected kidney.

Sugimura[3] found in twenty-five cases of cystitis, involvement of the lower end of the ureter in all, and demonstrated that the infection in all extended along the lymphatics and not in the ureteral canal. Bauersein demonstrated that when the ureters had been extensively dissected they subsequently became embedded in a mass of indurated tissue. In these two ways a certain amount of stasis is produced, conducive to infection in whatever way it is introduced.

In extensive operations for carcinoma, in addition to the other causes above mentioned, the large amount of wound secretion flowing over the urethral orifice tends to urethral infection.

From the cystitis, infection may reach the kidney along the urethral channel, through the blood or the lymphatics. In proof of the first assertion, Stoeckel offers the history of a case in which from the lower end of the ureter urine containing pus was obtained, while from a point higher was drawn clear urine. In spite of this, many authorities doubt the ascent of infection from the bladder. In many of the experiments in which the urethra is ligated, and infection, first of the bladder, and then of the kidney, occurs, this infection may as well be explained on the hematogenous theory as that of ascension of the ureter, the organisms gaining a port of entry through the wound caused by the ligation. F. Pawlik[4] is a believer in hematogenous infection of the kidneys in cases of cystitis.

A. Bauersein proved in his necropsies on the patients dying after the Wertheim operation for carcimona, that occasionally the kidney and the perinephritic tissue became infected through the lymphatics coursing along the ureter.

In the same articles he states that he believes hematogenous infection, with the port of entry the operative wound, is more usual than is generally believed. Lichtenberg[5] thinks too much stress has been laid on ascending infection of the renal pelvis, and considers the hematogenous route the more frequent.

Franz Jaeger[6] reports two cases of acute infection of the renal paryenchyma in kidneys which were the seat of chronic pyelitis. One of these appeared to be an extension upward through the urinary tubules and the other a hematogenous infection, the lesions being multiple abscesses in the cortex. Dr. F. E. Sondern of New York has in his collection a very fine specimen of acute hematogenous infection of the cortex of a kidney, the seat of chronic pyelitis.

There are many instances of postoperative renal infection in which there has never been any catheterization of the bladder, antecedent cystitis, nor previous infection of the urinary system.

In a footnote on a lecture on colon bacillus infection of the kidney Harry Fenwick[7] speaks of the frequency of infection following operations for hemorrhoids. Here three causes are present: (1) Surface lesions in an infected area; (2) congestion of the vesical neck; (3) retention of urine. Piero Poleenigo[8] reports a case of metastatic multiple renal abscesses, following operation for hemorrhoids.

It has seemed to me that renal infections are more apt to occur when there has been some operation on the intestinal canal, or when there is a wound that is apt to be contaminated by intestinal contents. Baisch contends that the colon bacillus is seldom the primary factor, but that it subsequently is added and then supplants the other organisms. The fact that so many of these cases follow wounds especially apt to be contaminated by intestinal contents, rather speaks against this claim.

Possibly the constipation incident to postoperative intestinal peristalsis, and the purging used to overcome this may account for some of these cases.

It has been demonstrated that the kidneys can excrete bacteria without being harmed, and it is necessary that the bacteria lodge and develop to produce pathologic lesions. The extent of the damage depends on the point of lodgment, the number and virulence.

The fact that many of these infections do not occur right after operation, but days later, make me think the infection is started from the breaking loose of thrombi from the vessels of the wound region. Points in favor of this are that usually after operation there is something indicating infection and that the acute condition is sudden.

The symptoms of infection of the kidney after operation depend on whether the pelvis is involved from an extension up the ureter, or the parenchyma is involved primarily through the blood. In the first instance there is apt to be a history of cystitis which on involvement of the pelvis of the kidney is attended with pain in the lumbar region and along the ureter, with a rise of temperature, with or without chill. Unless there is some retention in the pelvis, pain is absent, and there is little aside from moderate temperature to call attention to such an extension.

SYMPTOMS

In the acute hematogenous infections, which usually affect only one kidney, during convalescence, without any warning there is a sudden rise of temperature, sometimes preceded by chilly sensations or by a distinct chill. The temperature is generally marked by decided remissions. Pain may or may not be present in the affected kidney. Other constitutional symptoms are dependent on the severity and the character of the infecting organism. While the colon bacilli infections are attended with chills and high temperature, the constitutional disturbances are not so marked as in other infections. Often there is delirium and other evidences of disturbance of the sensorium. At first there is apt to be lessened frequency of urination due to decreased fluid output by the kidneys. Later when the ureter and bladder become involved there is frequency.

DIAGNOSIS

Early in the disease there is little in the urine to help in the diagnosis. At first it is usually high-colored, as in any other marked febrile condition. Bacteria may be isolated by culture. At the beginning there is not apt to be pus in the urine, and according to Münnich[9] this is especially so in the instances of colon bacillus infection. Later, pus casts, and at times blood, are to be seen in a urine that is highly albuminous. After involvement of the pelvis, pus is found in greater quantities.

SUMMARY

There are the three types of postoperative renal infection—through the blood, lymph-channels, and up the ureter. I think the ascending infection through the blood is the most common, and that the latter is much more frequent than is generally supposed.

The late occurrence of the infection, and the fact that most of the patients have had some rise in temperature immediately following operation, lend weight to the theory that the origin of the infection is from thrombi at the seat of operation.

Renal infections are probably more frequent than is imagined and will be detected oftener when the surgeon bears this in mind.

Below I have briefly given the histories of several cases. The hair-pin case does not properly fall within the scope of this paper, but it is inserted, as I believe the renal infection was hematogenous, the point of entrance of the bacteria being through a wound caused by the pin.

CASE REPORTS

Case 1.—Mrs. R., a patient whom I saw in consultation with Dr. Perry S. Boynton, to whom I am indebted for the notes and the privilege of reporting the case, had one child eighteen months before her operation, April 5, 1912. The examination of the voided urine before operation showed a few red blood-cells and a few pus cells. The operation was a curettage, trachelorrhaphy, perineorrhaphy, appendectomy for chronic appendicitis, and freeing of adhesions of the left tube and sigmoid. Symptoms were promptly relieved and the patient made a good recovery and left the hospital April 20.

While waiting for a car on an exposed corner the patient became chilled. Two days later she had a distinct chill, followed by fever and a dull aching pain in the left lumbar region. The next day Dr. Boynton saw her and found a large tender left kidney; at this time the temperature was 103 and pulse 120. Two days after this the right side was similarly affected. There was pus and colon bacilli in the urine. Dr. Boynton made a diagnosis of bilateral pyelitis. She was given intestinal and urinary antiseptics, and colonic irrigations. The condition persisted with exacerbations and remissions for six weeks.

June 8 she returned to the hospital and on June 12 and 14 I catheterized both ureters, obtaining from them urine with a moderate amount of pus and colon bacilli. Each time I irrigated the pelvis with 1:500 silver nitrate solution. In the next ten days the symptoms gradually improved, and she was able to leave the hospital June 26. After that she gained rapidly in strength and weight and became pregnant for the second time in October. She manifested no further urinary symptoms, and at the eighth month the voided specimen showed only an occasional pus cell.

Remarks: There were a few pus cells in the urine before operation, but as this was a voided specimen there is no certainty that they came from the urinary tract. The patient was catheterized twice after operation. It is possible that the chilling experience on the trip home may alone have accounted for the kidney infection, or may have produced a certain amount of renal congestion that would favor other factors. The apparent beneficial effect of the pelvic lavage is to be noted.

Case 2.—Mrs. A. L., aged 33, was seen first in February, 1910. Menses began at 14, occurring regularly every four weeks; moderate in amount, with severe pains in the lower abdomen on the second, third and fourth days. Soon after marriage she became pregnant and had to be aborted on account of pernicious vomiting at the third month; this was nine years ago. The menses after this were scanty. Within a few months after the abortion she had appendix and both tubes and ovaries removed. She is not certain of the conditions that necessitated such an operation.

A week or ten days after the operation patient had a chill, rise of temperature, and pain in the abdominal wound, which broke down. Three weeks after operation the patient took a full bath; following this she had severe pain in the right kidney region for a week. At first there was some blood in the urine, and marked frequency of urination. The patient thinks she had a rise in temperature for a few days at this time. After this she did not feel well, and about every four to eight weeks she had attacks of pain in the right lumbar region, sometimes associated with vomiting and sometimes with temperature. Had frequent urination and moderate pyuria after the primary attack. I saw her first three years ago, when a diagnosis of colon bacillus of the right renal pelvis was made. As this did not clear up promptly under the administration of hexamethylenamin, I catheterized the right ureter and instilled into the pelvis half an ounce of 1 per cent. nitrate of silver solution. Since then she has never had any pain in the kidney region and the pyuria and the frequency of urination have disappeared. The patient has since been in better health than at any time after the operation.

---

[9] Münnich: Arch. f. klin. Chirurg., xcviii.

Case 3.—Mrs. A. G., aged 27, seen through the courtesy of Dr. Edward Pinkham, was admitted to the hospital Dec. 8, 1908. She had had two children and two miscarriages, all uneventful. Her menstrual history had been normal until the month before entering the hospital, and in this time she had flowed, off and on, for two or three days at a time, profusely. For the week just before entering she had no flow.

December 9 she was curetted and the uterus swabbed with tincture of iodin and phenol (carbolic acid). She was catheterized three times in the thirty-six hours after operation.

December 17 she complained of some bladder discomfort, and the next day of some pain in the back. On December 20 she was still complaining of pain in the back, and there was a sudden rise of temperature in the early morning to 101.8 F., which increased to 104 in the afternoon. At this time the pain in the back seemed to be more acute on the left.

December 21 I employed the cystoscope and found a slight cystitis. Both ureters were catheterized and from both was obtained highly colored, turbid urine, containing pus and pus cells, more from the left. The same results were obtained on December 22.

As the patient was not improving, on December 24 Dr. Pinkham cut down on the left kidney, which was large, congested and was dotted with many small infarcts. An incision was made through the cortex into the pelvis.

Blood-counts on December 26 showed 14,000 leukocytes, 80 per cent. polynuclears, 15 per cent. small lymphocytes, 5 per cent. large. On December 28 the count was 11,000 leukocytes, 70 per cent. polynuclears, 19 per cent. small, and 5 per cent. large lymphocytes.

Following the operation the patient did not improve, and ran a high temperature, which gradually fell to normal Feb. 3, 1909, and there remained.

Until January 21 there was marked albuminuria, with hyalin, finely granular, at times pus, casts and much pus in the urine. Even at the time of her discharge, January 30, there was a marked amount of pus in the urine.

She returned to the clinic after six weeks, when we found that she had pus coming from both kidneys. This was cleared up after a few nitrate of silver injections of the renal pelvis.

I have to thank Dr. Burton Harris for the report of the next two cases. They were included in his paper on renal infections which he read at the Boston meeting of the Urological Society.

Case 4.—Mrs. M. W., aged 24, housewife, was seen in consultation with Dr. Charles Wuest and Dr. Rudolph Herriman Feb. 1, 1912. The records show that there had been an instrumental delivery of a normal child on Dec. 1, 1911. There had been no vesical or renal symptoms during pregnancy and the urine had shown no pus. A perineal tear had been immediately repaired. Catheterization was necessary for three weeks thereafter. One week after delivery she began to suffer from "chills and fever." The record states that there was no abdominal tenderness and that the heart and lungs were found normal. She had been under the observation of several physicians, who agreed on a diagnosis of post-partum septic endocarditis. The urine had shown a large amount of pus. Hexamethylenamin, 5 grains, was given every four hours from December 28 until January 17. Blood cultures were negative.

From December 28 until February 1 the temperature had ranged between 103 F. and 105 F., with marked morning remissions, and the pulse from 130 to 140, rather closely following the temperature curve. On February 1 the patient was septic in appearance and the mouth dry and foul; the temperature was 103 F. and the pulse 130 and of poor quality. We found no physical signs on which to base even a possible diagnosis of endocarditis. Examination of the abdomen was negative. There was moderate tenderness in both costovertebral angles. The bladder urine was acid in reaction and loaded with pus and bacteria. The blood-count showed 18,000 leukocytes, with 18 per cent. of polymorphonuclear cells. The blood cultures were negative.

Cystoscopy showed an intense general cystitis. No. 6 F. olive-tipped catheters passed easily to both renal pelves. The urine from the right side was acid, very turbid, contained a large amount of albumin and showed many epithelia from the convoluted tubules and renal pelves. Pus corpuscles and bacteria were present in abundance. Culture showed colon bacilli and *Staphylococcus aureus*. Their presence could not be ascribed to accidental contamination, for large clumps of cocci and bacilli were present in the fresh sediment of the urine obtained by the ureteral catheter. The urine from the left side was acid, somewhat less turbid but contained the same microscopic elements as that from the right. The colon bacillus was found in pure culture. On completion of the examination 10 c.c. of 10 per cent. argyrol was injected into both renal pelves and the patient kept in the Trendelenburg position for fifteen minutes. This was repeated on February 5, a 2 per cent. solution of argyrol being used. One-half c.c. of Van Cott's mixed vaccine was given on February 3, 7, 10 and 14. Her convalescence was uneventful. On March 1 the pus and bacteria had entirely disappeared from the urine, but the specimen continued to show albumin and occasional hyaline and granular casts and numerous epithelia from the convoluted tubules. At the time of her discharge on March 17 she was clinically cured and the urine showed no abnormalities.

Remarks: We have in this case a patient who had suffered from renal suppuration, mistakenly diagnosed as septic endocarditis. For more than a month the temperature had ranged from 103 F. to 105 F. I am of the opinion that a study of the chart shown in Figure 4 will convince the most skeptical that either the renal instillations, the vaccines, or probably both, had a beneficial influence.

Case 5.—Mrs. M. N., aged 22, housewife, was seen in consultation with Dr. Armin Sibbel on Jan. 1, 1912. Ten years previously she had suffered from acute articular rheumatism and endocarditis. There had been a mitral systolic murmur and hypertrophy of the left ventricle since that time. The records showed that on Dec. 6, 1911, there had been an instrumental delivery of a normal child. The perineum had been torn into the rectum, but was immediately repaired and healed *per primam*. Repeated urinalyses made until the delivery had shown no abnormality, with the exception of a faint trace of albumin. Following delivery the urine showed a few pus corpuscles and red blood-cells for several days, but this rapidly cleared up and was attributed to trauma. The temperature, which had been absolutely normal, began to show an evening rise to 99.5 F. The pulse, which had been running between 80 and 90 before delivery, suddenly shot to 130 and ran from 100 to 120 until December 14, the evening pulse-rate being about 20 above the morning. When discharged from the hospital December 23 the temperature was 99.2 F., the pulse 100, repirations 20. She looked and felt perfectly well and the urine showed no abnormality.

On the evening of December 29 she was suddenly seized with a severe chill and lancinating pain in the region of the right kidney. Vomiting and dypsnea were marked features. Dr. Sibbel was called in the morning of December 30 and found the patient suffering from orthopnea and moderate cyanosis. There was marked edema of both legs. The temperature was 102.2 F., pulse 140 and irregular. She complained of a dull pain in the right kidney, the lower pole of which could be felt, and was very tender both anteriorly and in the costovertebral angle. Digalen and hexamethylenamin (urotropin) were given.

At 4 p. m. January 1 the cardiac conditions had improved, the pulse having dropped to 110 and being of fair quality, but the temperature was 103.5 F. The patient complained of a dull pain in the region of the right kidney, and there was moderate tenderness in the costovertebral angle. The urine was acid, turbid, and analysis showed a large amount of albumin. There were many epithelia from the convoluted tubules of the kidney and a few blood-casts. Pus corpuscles and red blood corpuscles were present in moderate numbers. Stained smears of the sediment showed bacilli in abundance, which on culture were found to be colon bacilli. Blood culture by Dr. Holzman was negative. The leukocyte count was 12,000, with 88 per cent. polymorphonuclear cells.

Cystoscopy showed no abnormality in the bladder. No. 6 F. catheters passed freely to both renal pelves. The urine from the left side was clear and showed no abnormality. That from the right was turbid and showed the same chemical and cellular features as that from the bladder. The colon bacillus was found in pure culture. Phenolsulphonepthalein appeared on the left side six minutes after hypodermic injection; urea 0.021 per c.c. On the right side the dye appeared in nineteen minutes; urea 0.006 per c.c. Ten c.c. of 20 per cent. solution of argyrol was instilled into both renal pelves and the patient kept in the Trendelenburg position for fifteen minutes. A mixed vaccine 0.5 c.c. was given. On the following afternoon her condition was decidedly better, the temperature being 101; pulse 110. Both pain and tenderness were less marked. The vaccine was repeated January 3. January 6 the temperature was normal and the pulse 106. The edema of the legs had entirely disappeared. Renal pain and tenderness had quite subsided. The urine was clear but showed more than a trace of albumin, a few hyaline casts, many epithelia from the convoluted tubules of the kidney and a few pus and blood-cells. Weekly analyses of the urine showed traces of albumin with renal epithelia and an occasional cast for two months after the attack.

Dr. Sibbel reports that with the exception of occasional attacks of cardiac pain with the evidence of temporary failure of compensation, she enjoyed good health.

I was unable to make a further study of the functional capacity of the right kidney, as the patient refused instrumentation.

Case 6.—The patient, A. D., was first seen on account of chronic urethritis in 1909, when she was 19 years old. She confessed masturbation. The appendix was removed because of constant pain and tenderness over McBurney's point, but with no relief. She was radiographed for renal and ureteral calculi but none were discovered. The pelvis of the kidney was distended with fluid after the method of Kelly and the pain of which she complained was reproduced and exaggerated.

In 1910 her right kidney was explored. It was found to be 4½ inches long, with almost complete atrophy of the cortex of the upper three-quarters. It was removed and she was relieved of the symptoms.

In 1911 she went to the City Hospital for chronic urethritis, and while there had several operations on nose and throat, and a laporotomy for tubal disease. Shortly after this I heard of her as a patient with marked polyuria, the amount being 200 ounces a day.

In August, 1911, I took her in the Post-Graduate Hospital, as she had had retention for five weeks. Catheterization six to eight times daily was necessary, and 20 to 30 ounces were obtained each time. On one occasion she attempted to catheterize herself with a pencil from which the lead had been removed, explaining the act on the ground that she was in discomfort from over distention and could not wait for the nurse. The urine was of low specific gravity, no albumin and the phenolsulphonepthalein elimination was normal. Through suggestion she was relieved.

On Jan. 15, 1912, I saw her again. She told me that two weeks previously she had allowed a girl friend, who wanted to be a nurse, to catheterize her, and that to stiffen a soft rubber catheter she had placed in it a hair-pin. The next day the friend confessed that the hair-pin had escaped into the bladder. This was evidently untrue, as the irregularly bent pin which I found with the cystoscope could not have been inserted in the catheter. This pin was finely coated with a white deposit of salts, and the bladder only slightly hyperemic. She did not allow me to remove it.

On Feb. 3, 1912, she called me and reported that the day before she had two chills, fever and pain over the right kidney. The urine contained a large amount of pus, hyaline and granular casts. On February 4, through a Kelly endoscope, I removed the pin. By February 8 the temperature fell to normal, and in a week the patient was discharged. This is not strictly a postoperative renal infection, but is reported as I believe that the pin caused wounds of the bladder mucosa, through which infectious organisms entered the circulation and caused the kidney infection.

On March 1, 1912, she inserted another pin in the bladder which now, May, 1913, shows only slight incrustation—the bladder is only moderately hyperemic. In March, 1913, she broke a needle in her hand.

For the histories of the next two cases I am indebted to Dr. George Gray Ward, through whose courtesy I am able to report them.

Case 7.—Mrs. G. P. was operated on Aug. 26, 1908, for complete perineal tear and lacerated cervix; sustained in labor six weeks previously. The uterus was punctured accidentally with the curet and had to be repaired through an anterior colpotomy wound.

For the fifteen days following operation she ran a temperature from 99 in the mornings to 101 F. in the afternoons.

For the first nine days after operation it was necessary to catheterize the patient.

September 23, after nine days of normal temperature, with no apparent cause, the temperature was 100 F., and the same the next day. On the morning of September 25 it was 98.6 F., but rose by 4:20 in the afternoon to 103.4 F. September 26 it ran from 103.8 to 106 F., the low points being obtained with alcohol sponges. She began menstruating the next day, and then the temperature began to fall by steps and in four days reached normal, where it remained until October 8, the day preceding her next menstrual period, when it rose to 102.2 F. In two days it was normal and so remained.

She had no pain in the region of the kidneys. There were pus and pus casts in the urine and the colon bacillus was isolated by culture.

Treatment consisted in combating symptoms, and giving large amounts of water and hexamethylenamin. The patient made a good recovery and has since remained well.

Remarks: The patient was catheterized for nine days and had a rise in temperature for seventeen days after operation, indicating an infection. The late development of the renal condition and the possible association of the menstruation, as shown by two rises of temperature just before menstruation started, are to be noticed.

Case 8.—Miss J. N., patient of Dr. George Gray Ward, Jr., was operated on, curettage, Gilliam shortening of round ligaments and appendectomy having been performed. She gave a history of two attacks of appendicitis. Catheterized twice after operation. August 31 she complained of painful urination, and on September 2 the bladder was irrigated.

September 3 the temperature rose to 100.6 F. and the next day to 102.8. From the fifth to the ninth it ranged from 99 or 100 in the mornings to 101 F. in the afternoons. On the tenth, coincident with menstruation, there was an accession to 103.8, and 104 the following day. The day afterward the temperature was 101, and in the succeeding days dropped to 99.5. There was an exacerbation on the twentieth to 101.6, and on the twenty-first to 103.6. From then the patient rapidly improved, the temperature came down to 99.5, and so persisted until the time of her discharge on October 1. There was much pus in the urine. At no time was there any pain in the region of the kidneys.

Dr. Ward believes that the renal infection in both these cases was an ascending one.

I am indebted to my brother, Dr. J. N. Furniss of Selma, Ala., for the next case.

Case 9.—Mrs. T. B. M., resident of Tennessee, was admitted Feb. 20, 1913, suffering with an acute attack of chronic left salpingitis. First attack dates back four years following the birth of a child, at which time she was ill for several weeks with a pelvic inflammation.

Palliative treatment was employed until March 5, when the left tube, which was full of pus, and the appendix, which was bound down by adhesions, with a concretion about the middle, were removed. The patient was catheterized for the first three days after operation. Five days after the operation the patient began to have painful and frequent micturition, with thick, ropy mucus in the urine. This condition cleared up in a few days under bladder irrigations and urethral applications of 20 per cent. argyrol. The general surgical convalescence was excellent, the wound having healed by first intention. March 26 there was rigor and temperature ran to 103 F., with intense pain in the right loin, radiating to the right iliac region. The urine contained pus, blood and bacteria and was acid in reaction. The temperature ran from 103 to 100 F. until April 6. Pain and tenderness were incessant during this time. From April 6 to 10 the temperature gradually returned to normal and the patient left the hospital April 28 with negative urine and relief of symptoms. The treatment used was stock colon bacillus vaccine and large doses of hexamethylenamin, 10 grains each four hours.

The report from this patient June 8 was that she was well and still gaining in weight at the rate of 2½ pounds a week since leaving the hospital on April 28.

343 West End Avenue.

ABSTRACT OF DISCUSSION

Dr. J. W. Draper, New York: About eighteen months ago Dr. Braasch and I cut a number of ureterovesical valves in the dog. The reason for doing so was to find out if it were safe to cut this valve in the human being. We had heard so much about the value of this so-called "valve" in preventing ascending infection and bladder reflux that Braasch and others hesitated to cut it. The experiment, briefly, was as follows: After opening the bladder in the dog, it was a simple matter to raise it so that either one or both valves could be cut with a delicate pair of scissors. A cubical piece of anthracite coal was rubbed in the dog's feces and introduced into the bladder, which was then closed. These animals recovered with reaction and lived without any apparent discomfort. They easily held their own with the rest of the pack. They passed what may rightly be called pus in the urine. It answered the clinical description of pus, in that it contained living organisms and immense quantities of leukocytes. The organisms did not penetrate deep into the bladder wall and the animals may, therefore, be said not to have had a true cystitis. We were never able to show that there was any infection whatsoever of the kidneys in these animals, and many of them lived for a number of months. Moreover, hydronephrosis did not occur; the real factor in reflux prevention being the physiologic activity of the ureters rather than the mechanical action of the valve. Since returning to New York I have repeated these experiments and have again been unable to find, either grossly or microscopically, that in this type of experiment on healthy dogs any such thing as ascending infection occurs. Our experimental findings are therefore in exact accord with the clinical studies of Dr. Furniss. The post-mortem studies have been carefully made. The results were reported before the section on genito-urinary diseases in Atlantic City in 1912. These studies led us to consider that it is safe to cut the valves in human beings, that ascending infection under these conditions did not occur and that stones lodged in the caudad extremity of the ureter could safely be removed by valve section and without laparotomy. Bleeding may occur, as in a case verbally reported by Dr. Furniss, but it should not be severe. Infecting the bladder in dogs, then, with one or both ureterovesical valves destroyed, will not cause renal infection or degeneration. It should be impressed on us all, nevertheless, that we must be careful in drawing conclusions from the case of the healthy dog and applying them to the sick human being.

Nature Refuses to be Pigeonholed.—Referring to a case of clonic spasms in a man which it was impossible to classify, Dr. Savill says: "It is one more illustration of the fact that Nature—whether in health or disease, it matters not—refuses to be pigeonholed."—Thomas D. Savill, in (London) *Clinical Journal.*

TWO AND ONE-HALF YEARS' EXPERIENCE WITH SALVARSAN AND NEOSALVARSAN

WILLIAM THOMAS CORLETT, M.D.
Professor of Dermatology and Syphilology, Western Reserve University
CLEVELAND

From laboratory experiments on animals infected with the syphilitic organism it was at first thought that a sufficient amount of the synthetic arsenic compound known as salvarsan might be administered at one time to cause a complete sterilization or destruction of the spirochetes in man; hence the name under which it was possibly not most ethically heralded to the world—*therapia sterilisans magna.*

Contrary to what was first supposed, however, we now know that one dose is not expected to cure a case of lues even in its primary stage. But the value of these compounds, which have been used so extensively during the past two or three years, has been sufficiently proved to warrant the assertion that Ehrlich has made the greatest advance in the therapy of syphilis since it was first noted, several hundreds of years ago, that luetics improved under treatment with mercury.

From clinical experience it has long been known that preparations of iodin, especially the potassium iodid, while useful in causing certain late lesions of syphilis to disappear, have little or no appreciable effect in causing the elimination of the disease itself; in other words, possess no curative properties. Salvarsan, on the contrary, while capable of causing all of the symptoms of syphilis to disappear, has also a marked curative effect. This has been repeatedly demonstrated in my own service and by others in observing the effect of the drug when administered internally on the spirochetes of the initial lesion. While salvarsan has a marked curative effect, yet better and quicker results are obtained when mercury is also given than when either drug is given alone, a point that has been especially emphasized by Neisser and others.[1]

As might be expected with any new and unknown remedy so widely used and of such a powerful nature, fatal and unpleasant effects have been noted. In this second series,[2] up to the time of writing 220 cases have been treated with salvarsan and neosalvarsan. The first ten cases were treated with salvarsan injected intramuscularly. Since then, up to about the middle of 1912, most of them were treated intravenously with the alkaline solution. Since then neosalvarsan has been used exclusively, as the solution is prepared more readily and the immediate after-effects have been nil, except as noted later. This drug has also been used quite a few times intramuscularly, but this method is sometimes painful and may leave large, tender, indurated masses in the buttocks of one or more weeks' duration, which renders it less suitable than the intravenous route. In fat persons and in small children, however, it is the procedure of choice. A small 3-year-old child was treated in my service, for an innocently contracted lues, by intramuscular injections of 0.15 gm. neosalvarsan with excellent results, the child complaining of no pain.

The solutions of neosalvarsan for intravenous injections have been prepared, for the most part, with freshly distilled, sterilized water, although in a certain number a 0.4 per cent. saline has been used. In a few instances it was thought the water in passing through lead pipes after being distilled became contaminated and a Barnstead still was therefore installed in my laboratory. No ill results have been noted when water from this still was used. I think great care should be taken in every stage of salvarsan administration and that no one should attempt it without being thoroughly drilled and having suitable facilities at his command.

[1] Neisser, A.: Moderne Syphilistherapie mit besonderer Berücksichtigung des Salvarsans, Carl Marbold, Halle, 1912.

[2] Corlett, W. T.: Cleveland Med. Jour., December, 1910.

In the light of Milian's[3] recent report of a case of hemoglobinuria in a patient in whose treatment distilled water was used and in experiments on animals, it might be better to use the isotonic solution of neosalvarsan in a 0.4 per cent. saline water, although my own experience does not warrant this conclusion.

Most of the 220 patients treated have had three or four or even more injections. It has been a general rule with patients of average weight to give a first injection of 0.6 gm. neosalvarsan or 0.4 gm. of old salvarsan in men and 0.5 or 0.3 gm. in women, and if well taken to repeat in one week with a 0.75 gm. in women and 0.9 gm. (0.5 gm. and 0.6 gm. old salvarsan) in men, and once a week thereafter for at least two or three injections; after which there is usually a suspension of the arsenic therapy for several weeks or months. During this time advantage is taken of a course of mercurial treatment. I should like to emphasize the fact that in no case is the intramuscular administration of mercury, preferably in the form of gray oil, forgotten. Thus used in conjunction with mercury the results have been most excellent, not only in alleviating the patient's symptoms but also in regard to his general health as well as in the effect on the Wassermann reaction. The arsenic therapy seems to be of special value in primary and early secondary lesions. One injection of salvarsan will usually cause a practical disappearance of a primary lesion or of a secondary eruption. In some cases with old tuberculous lesions it works satisfactorily, then again shows little effect. In several cases of tabes and in one in particular, the results have been striking, so that the patient who formerly could hardly walk, has now thrown away his canes and gets around very comfortably. What the final results will be in some of these cases it is of course too soon to say.

With the first cases treated with the old drug there were frequently marked symptoms of gastric disturbance, chills, fever, headache, etc., but as time progressed the toxic qualities of the drug seemed to lessen so that during the first months of 1912 my patients showed few unpleasant symptoms from salvarsan. With the neosalvarsan the same absence of unpleasant sequelae has been observed. We are now giving dispensary patients intravenous injections, allowing them to rest for a time and then go home in a conveyance, if possible, and directing them to keep quiet until the next day or longer if necessary. We believe that this heroic combined treatment of clinical patients renders them innocuous to the community at the earliest possible moment. It has not been my good fortune, however, to maintain this favorable report in all cases, and I shall now take up these unfavorable experiences in detail.

REPORT OF CASES

Case 1.—*History.*—The patient, C. Y. R., a merchant, aged 57, weight 165 pounds, stated that six weeks previously a barber had cut his upper lip with a razor and that some time afterward a sore developed on the spot and gradually increased in size. He had some headache and general malaise, but otherwise felt well. He was admitted to the hospital May 6, 1911. At the time of entrance there was a marked swelling and induration of the upper lip on the right side, while on the inner border there was a red ulcerated area. The cervical and submaxillary lymph-nodes were very much enlarged and quite painful to the touch. Naturally, lues was thought of, but inasmuch as the family physician had used calomel ointment locally it was impossible to find the *Spirochaeta pallida*, and a diagnosis of syphilis was not made until the appearance of the secondary eruption some days later. The patient was given an intravenous injection of salvarsan, 0.6 gm., May 15, 1911, which was followed by marked flushing of the face and an uncomfortable "bursting" feeling in the head for several hours. He returned home, however, eight days later, much improved and gradually resumed his business. About the middle of June, or three weeks later, the patient noticed that he was unable to move the right side of the face, including the eyelid, which drooped, and the lips, without some effort and pain. Otherwise he felt well and the primary lesion had entirely healed. The trouble was believed to be a Herxheimer reaction and the patient was directed to begin inunctions of mercurial ointment; the symptoms cleared up within a week. He was then advised to take a vacation and proceeded to a fishing camp in Canada. While there, about July 24, he began to have intense frontal headaches and pain in the back of his eyes, with at times almost complete loss of sight. With these symptoms hallucinations developed. He once more entered the hospital.

Examination.—At the time of entrance, Aug. 8, 1911, his general physical condition was good, but his sight poor, and an examination made at that time by Dr. B. L. Millikin was as follows: "Sight right eye, 6/24; left eye, 6/24-1. Both eyes tested with circles 1.5 cm. in diameter for white, red and green give a fairly good field in all directions and with proper relations to one another. The objects grow brighter as the fixation point is approached for colors and white, showing no scotomas. Ophthalmoscopic examination shows the media all clear, pupils rather small and reacting promptly to light and accommodation. The disk is round, good sized, broad central physiologic cup. There is a slight pigment ring. The arteries and veins are both good sized and normal in distribution and not tortuous. The temporal half of both eyes shows somewhat pale, but no marked striations."

Treatment and Course.—The patient was not given salvarsan because of the hardened condition of the arteries and the marked reaction he had shown, but was immediately put on daily injections of mercury biniodid ¼ grain and later mercury chlorid from ⅛ to 1/6 grain. He was discharged September 20 much improved and since then has had mercury salicylate injections at regular intervals and is doing well.

Diagnosis.—"Herxheimer reaction followed by neurorecurrence," following chancre treated with salvarsan. Recovery.

Case 2.—*History.*—The patient, J. H. D., was an illustrator, aged 29, weight 137 pounds. The personal history is negative aside from a luetic infection of seven years' duration, for which the patient had taken large amounts of mercury by the mouth, but for two or three years this treatment had not reacted well. He was troubled with ulcerations of the throat which were very obstinate in healing.

Treatment and Course.—Being consulted by his family physician I advised the use of neosalvarsan. The patient received an injection of No. 4 (0.6 gm.) neosalvarsan intravenously, Nov. 17, 1912. He reacted well and went back to work the next day. Seven days later the patient received a trifle less than No. 6 (0.8 gm.) neosalvarsan intravenously. Shortly afterward he was taken with paroxysms of vomiting which continued all night and the next morning. Through some error the patient was allowed to go home although still vomiting and having a temperature of 101.5 F. During the next two days the vomiting continued and the patient had severe chills and fever with twitchings of the muscles. I was notified of his condition on the third day after his injection when he had a temperature of 102.5 F. He was perspiring copiously and was in an almost continuous chill with marked chattering of the teeth. As it looked like an infection the patient was removed to the hospital at once where a blood-culture was made and found to be sterile. At that time a blood-count showed 8,000 leukocytes. The next day the patient was somewhat improved and was able to take some liquid nourishment, but his body was covered with a general erythematous eruption and an extensive herpes had appeared on the right cheek. On the sixth day he complained that his left leg was helpless and that his body was numb below the waist-line.

---

[3] Milian: Bull. Soc. franc. de dermat. et de syph., December, 1912.

First Examination.—Nov. 30, 1912: Heretofore the patient had been restless and vomited so much that a careful physical examination was impossible until to-day, thirteen days after arsenical treatment. The skin is of a reddish, somewhat erythematous hue. No jaundice, anemia, edema or cyanosis is observed. There is a herpetic eruption on the right cheek, as previously noted. The conjunctivae are somewhat injected, but the movements of the eyeballs are normal in all directions. There is no ptosis, strabismus nor nystagmus. The palpebral fissures are equal on the two sides. The pupils are irregular and the reaction to light and accommodation is sluggish. The tongue is coated and tremulous, but protrudes in the median line. The right posterior pillar of the fauces is bound down by old cicatricial adhesions. The heart and lungs show nothing abnormal, nor does the abdomen reveal any enlargement of the liver or spleen. The patient is unable to move the thighs, legs, feet or toes, although as yet there is no atrophy of the muscles noted. The knee-jerks are present, of normal intensity and equal on the two sides. The ankle-jerks are very difficult to obtain and there is no Babinski phenomenon. The biceps, triceps and supinator longus reflexes are all present and hyperactive, but equal on the two sides. The pain, temperature and epicritic senses are lost below the distribution of about the tenth dorsal nerve segment and there is some tenderness over the nerve trunks. The vibratory sense is present in both lower limbs. To-day the patient complained of some fulness of the abdomen and examination revealed a full bladder and on catheterization forty ounces of urine were removed. It was found necessary to catheterize the patient four times a day thereafter for several weeks. The urine showed a slight trace of albumin, a few white blood-cells, together with granular and hyaline casts.

Record by Days.—Dec. 1, 1912: The patient is much worse. There is a marked puffiness of the eyelids and face and he complains of pain in the joints, and a marked loss of strength in arms and hands. There is a loss of sensation below the innervation of the eighth dorsal nerve segment and the pain sense in the upper extremities is diminished. The knee-jerks have disappeared and the biceps, triceps and wrist-jerks have notably diminished since yesterday. A lumbar puncture was done and 6 c.c. of clear fluid removed under no pressure. The pipet count was normal and arsenic was detected in both the urine and spinal fluid by Dr. J. J. Pilcher of the pharmacology department of Western Reserve University.

Dec. 5, 1912: Patient is markedly jaundiced and has a slight decubitus on the right side; stronger in the arms but still unable to move the legs.

From this time on the patient began slowly to improve, the reactions to electricity, etc., varying somewhat from time to time. The jaundice cleared up about December 18 and January 1 the urine began to run of itself, but the patient was unable to control it. As the Wassermann reaction was strongly positive he was put on daily injections of mercury bichlorid one-fifth grain and about the middle of January he began to be able to move the thigh and leg muscles of the left leg and wiggle the toes of the right foot.

Second Examination.—By Dr. C. W. Stone of the neurologic department of the Western Reserve University, Feb. 2, 1913: Plantar stimulation of the left foot causes plantar flexion of the great toe with dorsal flexion of the second and third toes and plantar flexion of the fourth and fifth toes. Oppenheim and Schaeffer tests cause some reaction. There is a positive Mendel (Bechterew) on the left foot and no Babinski on either side, although suspicious on the left. The patellar reflexes are present, active and equal on the two sides. Ankle-clonus present on both sides, but more so on the left. Ankle-jerk is present on both sides. There is a dermatographia on both sides of the abdomen.

Sensation: Temperature as follows: Above the knee he perceives both heat and cold on the right leg and also below the knee for the upper two-thirds on the inside and upper one-third on the outside. In these areas it is uncertain, but below them neither is perceived. On the abdomen both hot and cold are distinguished above the umbilicus and below it on the right side, but both are uncertain on the left side below the navel. On the entire left leg both heat and cold give a sensation of warmth.

Pain: Complete analgesia of entire left leg, although patient feels touch of the pin but no pain. The pain sense is distinctly less on the right side below the middle of the thigh and becomes increasingly less as one approaches the foot.

Vibration: The vibrations of the tuning-fork are perceived in both legs, and on both limbs equally well.

Touch: Probably no diminution in the touch sense. Usually the brush feels the same on the legs as on the trunk though sometimes less. There is no disparity in the acuteness of the two sides.

Electrical Reactions: Galvanic. Quadriceps with a current of eighteen milliampères does not respond to KCC but does to ACC. It is better on the left than on the right side. The vastus internus with the same current responds to ACC, but not to KCC on the left side. Tensor fasciae femoris—ACC is greater than KCC on both legs, but KCC is absent on the left leg with 25 milliampères current. Peroneals—ACC is greater than KCC on both legs though KCC is present in both limbs.

Faradic Current: The quadriceps respond on both sides, but only with a strong current on the right side. The peroneals, gastrocnemii and solei all respond promptly.

Progress of Case.—Feb. 24, 1913: The patient is slowly but steadily improving. The decubitus is gradually closing in and the patient is around in a wheel-chair.

March 15, 1913: The decubitus is entirely closed in and the patient discharged. He has been taking daily injections of mercury biniodid one-fourth grain for a long time and his Wassermann reaction is now negative. Patient instructed to have daily massage at home.

April 8, 1913: Patient has been visited weekly and he is improved slowly. He finally is able to control the bladder and can now stand on his feet.

Diagnosis.—Arsenic intoxication due to idiosyncrasy or more probably to lack of elimination.

Case 3.—Miss E. F. G., patient with a luetic history, was referred by her family attendant for treatment by salvarsan. At the time of admission she was extremely nervous and had headache, but was otherwise well and weighed 106 pounds.

Treatment and Course.—Feb. 2, 1913, she was given an injection of No. 4 (0.6 gm.) neosalvarsan intravenously. The next day the patient began to complain of increased headache, general malaise and loss of appetite while she had a temperature of 102 F. with a pulse of 110. These symptoms kept up until February 6, when the patient had a temperature of 104 with a pulse-rate of 110 to 120, a slightly injected throat with a white blood-count of 3,000 and an enlarged and tender spleen. Otherwise the examination revealed nothing and a blood-culture was done. The next day the continuous fever began to drop and the patient felt better despite the fact that on February 8 the spleen was still enlarged and the white blood-count was 4,000. The blood-culture was negative. Patient was discharged February 11, well, the urine having shown nothing at any time.

Case 4.—Miss L. S., aged 21, weight 112 pounds, presented a small node-like protuberance on the anterior surface of the tibia of one year's duration, the nature of which was obscure. Previous history was good; patient's father died at 35 of pneumonia. The patient had been treated with potassium iodid but the discomfort continuing, the case came under my care.

Treatment and Course.—As two Wassermann tests at different times and by two competent serologists showed a positive reaction she was given on May 17, 1912, 0.45 gm. neosalvarsan intravenously. This was followed by severe reaction and a marked jaundice occurred on the third day. This disappeared in a few days and the patient returned home. No change in the nodule was observed. Two weeks later a second administration of No. 4 (6 gm.) neosalvarsan was given without untoward symptoms but without producing any change in the tumor notwithstanding that neosalvarsan was alternated with mercury.

In two other cases a slight jaundice has followed the use of salvarsan. In one case of pemphigus foliaceus, 0.4 gm. salvarsan intravenously was followed by no appreciable results.

FATALITIES REPORTED FOLLOWING USE OF SALVARSAN

Up to last November about 600,000 ampules of neosalvarsan and 3,000,000 of salvarsan[12] had been sold. Naturally with such a powerful drug, used in such a large number of cases, we must expect some unpleasant results; as nearly as can be ascertained about 124 deaths have been authentically reported to March, 1913.

In this country two other deaths, undoubtedly overlooked by foreign writers, have been described by Ruh[18] and Newmark.[9] These statistics do not include many other deaths in which physicians have not reported from fear of unpleasant results, imagined reflections on themselves, etc. Placing the deaths at 200, there has been about one death for each 2,000 injections, but, as we shall see, some of these should be omitted as they are thought not to be due to salvarsan.

FATALITIES DIRECTLY DUE TO SALVARSAN

From the symptomatology of these fatal cases they appear to belong to several types, more or less shading into one another. A few have been described in which the patient dies suddenly after the injection, having shown few or no symptoms. Probably the most common, however, is that of a subacute type coming on in a day or so with headache, weakness, vomiting, often incontinence of sphincters, coma, dyspnea, cyanosis and death in from three to four days. In this type one generally finds a serous meningitis and often some small ruptured vessels at the base of the brain. The French have reported this finding several times and say that often no other lesions are to be found.

In some of the cases, of which the one described by Ruh[18] can be taken as an example there is a total or partial suppression of urine, with albuminuria, hematuria and death. In the one reported by him the patient, five days after having had an intravenous injection of salvarsan, died from anuria and toxic symptoms of uremia. He found at necropsy evidences of a severe intoxication present mostly in the kidneys and liver, which showed degenerative changes and proliferation of the parenchyma—these changes being similar to those produced by experimental arsenic poisoning.

Busse and Merian's[19] case was also much like this and necropsy showed cerebral edema with hemorrhages, thromboses and inflammatory lesions in the white substance of the brain and cord. There was also an acute nephritis and hemorrhagic lesions in several organs. They concluded that their case was an acute arsenic poisoning as the kidneys showed extreme degeneration of the parenchyma with swelling and desquamation of the glomerular epithelium. The spleen also showed swelling of the pulp with hemorrhages and beginning areas of necrosis. Lesser[20] and later Lube[17] call attention to the presence of convulsions in some of the cases. In twelve of Lesser's eighteen cases the convulsions came on shortly after the injections and nine of these patient died; while in the other six the convulsions appeared later. Thus in one case eight weeks after the third injection the patient was suddenly seized with epileptic attacks lasting a short time. Later this patient had several injections of salvarsan but with no symptoms following.

Concerning the cause of these postoperative troubles it may be best first to give a brief survey of the opinions of different men after which they might be taken up more in detail. Emery[21] has during the past year been working on the influence of contaminated water on the organism when intravenous injections are given. He finds that even infinitesimal quantities of copper and lead in freshly distilled water are liable to cause toxic symptoms and he advises the use of Jena glass for the distilling apparatus so that none of these salts will be dissolved out by the water in the process of distillation.

Coming now to the question in detail, there is one class of ill results appearing very acutely after the injection, which can be explained as an acute arsenic poisoning and on that basis alone. Ruh's case was such a one and Busse and Merian's another. Darier's two cases can be explained most easily under this heading and unquestionably that of Wolff and Mulzer's; in fact, they admit it themselves. Hallopeau[23] feels, from his experience, that alcoholism predisposes to arsenic poisoning due to the changes in the liver and in his case he believes this had much to do with the fatal result.

It has been found by different investigators that the bulk of the neosalvarsan is excreted in the first three or four days and of course anything hindering this excretion, for example, cirrhosis of the liver, would predispose to an intoxication on the taking of the second dose. Wechselmann[24] believes the bad results are due to a retention of the drug in the blood from some cause and it may be that this took place in Case 2 of my series. Be that as it may, the recent work of von Marschalkó and Veszprémi[25] shows quite conclusively that the tolerated dose of 0.01 gm. salvarsan, 0.015 neosalvarsan, per kilogram, as determined by Hata for animals, is much too high. Animals receiving 0.015 per kilo died in several hours and those receiving from 0.011 to 0.012 gm. per kilo in two to two and one-half days. The necropsies showed the exact analogy with the so-called meningoencephalitis so much emphasized by the French—dotted hemorrhages at the base of the brain, stasis, hyalin thrombosis, and hemorrhages without inflammation. These findings have also been lately amplified by these men in another place. They find when less than 0.008 gm. per kilo is injected the animals always live. They conclude that all the deaths can be explained on the basis of an arsenic intoxication and in a later paper[26] urge that the dose of 0.4 gm. should never be exceeded.

According to some men these "neurorechutes" or "recidives" are seen most frequently in cases of cephalic chancres as in Case 1. Desneux and Dujardin[30] on Bayet's service saw seven cases of "neurorecidives" after cephalic primaries and they usually began with intense headache, as Werther and Benario[31] have already noted. They started in from one to four months after the injection, at a time when practically the last remnant of arsenic had been excreted, and these men considered that the cases were exclusively luetic in origin.

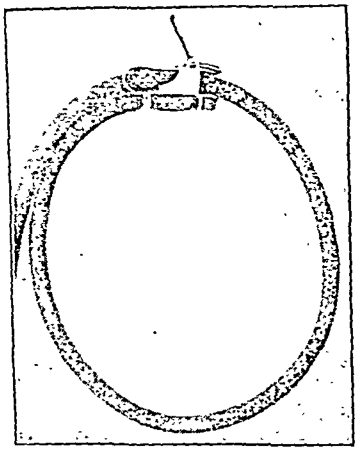
[30] Desneux and Dujardin: München. med. Wchnschr. 1911, No. 23, p. 1245.

As to their true causation there is still some difference of opinion. Some believe they are due to a toxic action of the salvarsan on the nerves, while others think they have nothing to do with salvarsan. Again others believe that while they are of a luetic nature, yet the salvarsan, in its action on the nerves, has caused a *locus minoris resistentiae.* Still another group of observers, headed by Ehrlich himself, believes that they are due to the progressive germination of a few *unkilled spirochetes.* Neisser takes the ground that the salvarsan therapy has nothing to do with the "neurorecidives" except in this way—that in some persons, unfavorably influenced by the arsenic therapy, these nerve lesions come on earlier than they would otherwise. Benario has attempted to show that the same ill results were noted, and as frequently, after the use of mercury as after the beginning of salvarsan therapy. In concluding this consideration it seems evident that the "neurorecidive" or "neurorecurrence" is of a luetic nature, but it is hardly to be doubted that the salvarsan plays an important rôle both as to time and character of its appearance.



ACCIDENTS CLASSIFIED

Accidents following the use of salvarsan may be classified as follows:

1. Those coming on very shortly after the injection with symptoms of an acute intoxication and necropsy findings of serous meningitis, hemorrhages, and frequently lesions of the kidneys and liver, lesions such as one finds in experimental arsenic poisoning.

2. Those coming on in from two to four days with symptoms of nerve paralyses, at times deafness, dizziness, poor hearing and even loss of consciousness, due to the Herxheimer reaction. It is explained by the killing of the spirochetes with consequent loosening of their toxins, and resultant edema and swelling of the parts affected, causing severe damage in such uncompressible tissues as the brain or nerves running through an osseous foramen.

3. Those coming on within from several weeks to months after the injection with symptoms of nerve paralysis and to be classed (1) as a "neuro-exacerbation" or "neurorechute," in which there is the lighting up of a hidden process already working or (2) as a neurorecurrence "neurorecidive," in which there is a genuine starting up of a new lesion. Both these processes while luetic in character are associated with the arsenic preparations at least as to time and mode of their appearance.

CONCLUSIONS

I do not wish to convey the idea that the use of salvarsan is to be discouraged. On the contrary, I believe that when the drug is properly used and by experienced persons it is a most valuable weapon against the *Spirochaeta pallida.* To insure against untoward results, however, one must exercise care as to the selection of cases and after ascertaining that no physical disqualification exists, one should further exercise care in not giving too large doses. From my experience, I would advise that treatment be begun with a small dose and gradually worked up by succeeding injections not to be given oftener than once a week. Great care should be taken as to the purity and sterility of the distilled water. The reaction of the patient should be carefully watched and, if very severe, further injections should be given with *exceeding care.* In cases of cephalic chancres one should institute salvarsan therapy with the greatest caution. If these precautions are taken, the result will be with rare exceptions most gratifying and, if the drug is used in conjunction with mercury, the result will be much quicker and surer than with either alone. *Again, there* are many obstinate cases that will react only to this combined line of treatment. As to the relative therapeutic value of the old and the new salvarsan I have been unable to detect any difference.

Finally, every physician having had accidents from the use of salvarsan should consider it his duty to report them, for in this way only can we arrive at a fuller and better knowledge of this the last great stride in overcoming syphilis.

A SIMPLE TOURNIQUET

F. D. Austin, M.D., Charlotte, N. C.

This device is made of a piece of ordinary rubber *tubing* and a clamp from a fountain syringe. The illustration shows the details, making a description unnecessary.

GOLF-BALL BURN OF EYE

H. E. Thomason, M.D., Kansas City, Mo.

E. F., boy aged 13, in February, 1913, thrust his knife into the center of a golf-ball. Out spurted a liquid directly into the right eye. Dr. Lee Haynes, who was summoned, sent the boy directly to my office; he arrived about two hours after the accident. There was marked swelling of both conjunctivae, so that the lids were everted. Cornea was milky-white; only light perception was present. There was agonizing pain, for which a 4 per cent. solution of cocain was instilled. Patient was sent to South Side Hospital with instructions to use 1 per cent. solution of atropin sulphate, sterile olive oil and cold application, followed in twenty-four hours with hot. On third day I noticed a detachment of both palpebral conjunctivae. This I allowed to remain to prevent symblepharon while a new one formed. The conjunctiva was removed on the tenth day. The epithelial layer of cornea sloughed on the fourth day and was removed.

The result so far I consider good as there is only a slight symblepharon at outer and inferior angle of the eyeball. Vision unaided 20/40 with a sphere plus 1 20/30. There is a small leukoma on cornea at inner canthus. An ointment of 5 per cent. dionin has been the principal treatment since the acute symptoms have subsided.

317 Argyle Building.

What Is Courage?—The bravest men are not those who are insensible to physical fear, but those who master it by courage of spirit; the purest and noblest are not those who have never felt the temptations of the body, but those who have resisted them.—*The Outlook.*

HAVE SPERMATOZOA OTHER FUNCTIONS THAN THAT OF FERTILIZATION?

Our widening view of the possibilities and omnipresence of immunity reactions in physiologic as well as pathologic processes gives us an understanding of the significance which may lie in a recent study of Kohlbrugge of Utrecht on the fate of spermatozoa in the female organism and their potential influence on both mother and offspring.[1] The prevailing idea has been that of the millions of spermatozoa introduced into the mammalian female — about two hundred million in the human — one single spermatozoon, more active or more fortunate than the rest, reaches the goal and becomes immortalized in a new being, while all the rest die and pass out through the route by which they have entered. It has been known to the zoologists that in at least some of the invertebrates the spermatozoa invade the entire body of the female, penetrating even the viscera, and sometimes perforating the cuticle from the outside to reach by this direct route the genital tissues. In some species, furthemore, it has been observed that not merely a single spermatozoon, but many spermatazoa, may enter the ovum.

At one time there did exist a belief, founded purely on speculation, that the spermatozoa of the mammal invaded the entire generative tract, and perhaps the entire body of the female; but this idea was current over a century ago, and entirely discredited in more recent times. Now Kohlbrugge has found evidence which seems to indicate that perhaps the ancients guessed better than their descendants reasoned. He has detected in such mammals as mice, rabbits, bats and in some other vertebrates the spermatozoa invading all the folds of mucous membrane in the uterus and tubes, penetrating the epithelium and invading the underlying connective tissue. He has also observed that they may enter the developing ovum for some time after the first stages of multiplication of the impregnated cell. The observed and possible effects of these activities of the spermatozoa are many. The cells of the uterine mucosa which have been entered by the sperm seem to be stimulated to growth, indicating that this may be a factor in the preparation of the mucosa for the embedding of the egg and the formation of the decidua. It is also possible that these foreign cells entering the tissues may lead to immunologic reactions of significance, such as the occurrence of corresponding diatheses in husband and wife, the reputed resemblance which develops in married couples, not only in psychic, but also in physical characteristics, and possibly other yet undetected biologic interrelationships. This is an almost untouched field which may yield important results when once worked over.

The entrance of additional spermatozoa into the fertilized egg may also have important results. Possibly they confer added stimulus to normal growth, or lead to abnormal developmental changes of importance for teratology; or, again, they might introduce either nutritive substances or pathogenic agents into the egg. In case of spermatozoa coming from a different male than the one who fertilized the ovum, *there are unlimited possibilities to be imagined in the way of adding characteristics of the second male, or modifying the growth of the ovum through its reaction to alien sperm, etc.* It would also be possible in this way for diseases to be present in the child which were not acquired from either of the actual parents. The simple observations of Kohlbrugge are of such a character as to stimulate speculation leading into remote fields; so much so, indeed, as to obscure the fact that they are as yet unconfirmed, and that the results ascribable to the wandering spermatozoa are entirely hypothetic. Even if the male elements do invade the female tissues and the fertilized and growing egg, it does not necessarily follow that any effects of importance result therefrom; but the process of generation is so mysterious that any new suggestions are bound to lead to extravagant speculation.

IS ALCOHOL A FOOD?

It has been extremely difficult in the past to approach the subject of the value of alcohol to the human economy in a way that would lead to an entirely dispassionate estimate of the part which it may play. The question is unusually complex because alcohol may affect the body physiologically or pharmacologically in a variety of ways quite apart from its possible rôle as a nutrient substance. The reply to an inquiry on the subject is likely, therefore, to be tinged with the impressions that are left by the particular aspect of the subject under consideration, sometimes without regard to other equally important considerations. The physician looking primarily for certain immediate responses which he desires to accomplish in a diseased organism may, for example, tend to overlook other more remote effects seemingly unrelated to his immediate interest. One writer will thus emphasize the beneficial features of the use of alcohol; another may with equal readiness see only its detrimental aspects. Again, an investigator, impressed with the dire consequences for which alcohol may be responsible in relation to the nervous system, may utterly overlook the ready oxidation of alcohol in the organism and the physiologic possibilities suggested thereby in respect to energy utilization. Questions of dosage are clearly appreciated in any discussion of the action of drugs; and every therapeutist well realizes that small amounts of toxic compounds, like arsenic or strychnin, may exert most beneficent effects under appropriate conditions. The discussion of the subject of alcohol, however, is all too frequently so pervaded with passion and partisanship that the open-minded student finds himself embarrassed in attempting to steer a safe course between bias on the one side and ignorance on the other.

---

[1] Kohlbrugge, J. H. F.: Die Verbreitung der Spermatozoiden im weiblichen Körper und im befruchteten Ei, Arch. f. Entwcklngsmechn., 1912, xxxv [illegible]

In 1902 Atwater and Benedict furnished a notable contribution to the physiologic aspects of the alcohol question.[1] They investigated the influence of "moderate" amounts of alcohol on man—quantities equivalent to what would be supplied in a bottle of claret or in 6 ounces of whisky. It was clearly and conclusively shown that 99 per cent., that is, practically the entire amount, of such intakes of alcohol per day were actually oxidized in the body. The proportions of food and the several kinds of nutrients digested and made available for use in the body were practically the same in the experiments with and without the alcohol in the diet. In every case the law of conservation of energy was obeyed. The potential energy of the alcohol (which yields about 7 large calories per gram) was transformed into kinetic energy in the body as completely as that of ordinary nutrients, and ultimately left the body as heat, precisely as is to be expected. But more striking than these generalizations was the fact, clearly brought out by Atwater and Benedict, that alcohol is efficient in the protection of the body-fat from consumption. There was no evidence, from the point of view of energy, of any considerable difference between the alcohol and the isodynamic amounts of fat and carbohydrate which it replaced. The efficiency of alcohol in protecting body protein, though evident, was not equal in this respect to isodynamic quantities of the ordinary nutrients.

These experiments show that alcohol is burned up in the body like the other foodstuffs, but they by no means thereby prove that its energy may appear in the form of muscular work as well as heat. Herein lies a distinction frequently overlooked by those who are not thoroughly conversant with the subject of metabolism. A compound may be burned up and its energy completely converted into heat. But the living organism requires more than heat; part of the energy furnished to it must at some time be capable of conversion into movement—into muscular work—if the functions of the body are to be carried on. It has often been urged by the partisans of the anti-alcohol propaganda that alcohol can never function as a true nutrient because, granting that it can be oxidized in the body, its energy is never transformed into muscular work. At best, they remark, it furnishes useless heat to an already overheated organism. The classic experiments of Atwater and Benedict do not prove that alcohol may furnish the energy of muscular work, even though they make it "highly probable."

We often hear the statement made that the "alcohol calories" fail to serve any useful end when they are burned in the body. We are told that alcohol, in any amount whatever, is a poison. Poisons do not become essential integral parts of living cells; so that on this basis one may conclude that the calories represented by alcohol appear merely as waste heat without furnishing to the economy anything of real advantage when such a "poison" is burned therein.

Durig[2] of Vienna, a competent student of the problems of metabolism, has again approached the question of the extent to which moderate amounts of alcohol can really supplant carbohydrates in nutrition. He selected conditions presumably particularly favorable to the preferential use of the carbohydrate in the metabolism, in case the organism were really not adapted to the satisfactory utilization of alcohol. The subjects were given large amounts of sugar with and without the addition of alcohol. The experiments were so planned that if the combustion of alcohol merely leads to waste heat its products would be added to that of the sugar which was always available in abundance. The results seemed to show that there was no waste under these conditions. Despite the surfeit of sugar available it was spared from destruction for liberation of energy by the alcohol which was burned to replace the carbohydrate. It is sometimes asserted that such conservation of foodstuffs when alcohol is ingested is due not to an actual replacement of nutrients, but to the toxic inhibitory effect of the alcohol whereby all the metabolic processes are decidedly diminished. Nutrition is represented as being in a sense paralyzed. This view is combated by Durig.

In emphasizing these facts regarding the behavior of alcohol in nutrition one cannot point out too emphatically that they do not commit us to the dictum that alcohol is an excellent or even an advantageous food. To say that alcohol may be a food is not to deny that it is a dangerous one. If it is given too freely its oxidation is incomplete and, what is more important, the untoward nervous effects become prominent. In ordinary conditions of health there is no occasion for the use of alcohol, and its introduction into the regimen of daily life can scarcely be defended on the grounds of nutritive needs. Dr. Meltzer has said that "alcohol in health is mostly a curse and in sickness mostly a blessing." The conscientious physician is entitled to know the truth in regard to it. His prescription of alcohol should be based on a clear conception of its action and its limitations.

"NATURAL" AND SYNTHETIC SALICYLATES

From the title of the Council on Pharmacy and Chemistry the natural but erroneous inference is probably drawn that it deals with laboratory matters exclusively, questions of therapeutics which must be answered at the bedside not being considered. The fact that laboratory investigation has often sufficed to fix the status of a preparation, the chemical evidence of its fraudulent character being sufficient to warrant no further investigation by the commission, is to a great extent responsible for this mistake. Questions of composition and pharmacologic qualities are determined by chemical analysis and animal experiments. Laboratory experiments must decide whether the claims are *true or false*. In some instances, however, laboratory investigations are not sufficient and attempts must be made clinically to show the true therapeutic worth of the product. In such cases, if the matter requires wider investigation than can be given by its clinical members, the Council submits the question to its Staff of Clinical Consultants, whose experience and judgment are acknowledged, and they determine whether or not the clinical evidence submitted is sufficient to sustain the therapeutic claims made. In this way every phase of the questions submitted to it is settled by the Council.

Some time ago the Council on Pharmacy and Chemistry authorized a cooperative investigation of a question which has long been disputed without conclusive results: Are the "natural" salicylates superior in any way to the synthetic products? The various steps of the investigation are reviewed in the report of the Council in this issue.[1] They involve, first, a chemical examination of the product; second, a pharmacologic examination, and third, a critical survey of the literature. The chemical examination of the products on the market showed no chemical difference between the natural and synthetic salicylates; the pharmacologic examination showed no difference in the action of the products; an analysis and critical survey of the whole literature on the subject showed that from previous studies there is no ground for the conclusion that the natural salicylates are superior in any way to the synthetic. With these preliminary data, it was justifiable to proceed to the clinical investigation. This was planned so as absolutely to avoid the factor of personal bias which has wrecked many similar investigations. A large number of clinicians, including many who had decided opinions on the question, were invited to participate, with the condition that they should not know the origin of the different samples used by them until after they had rendered their reports. A sufficient number responded to make the results representative. The conclusions are decisive and unmistakable. No investigator could distinguish which of the powders supplied to him were natural and which were synthetic. The collective tabulation showed that the natural and the synthetic products give almost mathematically the same percentage of therapeutic results, in fact, in all the phenomena recorded.

The question would certainly seem to be decided: Natural salicylates are in no way superior to synthetic salicylates. The value of cooperative clinical investigation of this and similar questions is well illustrated by these investigations. The decisive result of the report is due to the willingness and enthusiasm of the investigators, who deserve the highest credit and thanks for their collaboration with the Council.

A VIEW OF ANESTHESIA

Broadly speaking, the term "anesthesia" *may be used* to designate any temporary or reversible lowering or loss of the vital responsiveness, or of the normal automatic vital activity, under the influence of certain artificial substances or conditions. This property of complete reversibility, whereby the normal activities of the organism may completely return when the influence of the anesthetic has passed off, distinguishes it clearly from those irreparable losses of physiologic power which are allied to death. It is only natural that so unique a manifestation should incite investigation of the inherent nature of anesthesia. Consequently there have been various theories of anesthetic action.

The fundamental factor in anesthesia is a loss of what biologists term the irritability of cells or tissues. They no longer exhibit a characteristic response to stimuli to which response is ordinarily obtained. It would lead us too far to take into consideration here the many conditions which are known to alter or abolish the irritability of an organism. Modifications of temperature, certain electrical currents, fatigue and mechanical shock are among them. Irritability may be more easily modified, however, by the use of chemical substances than by any other means; and for the medical investigator interest here centers chiefly in a group of largely unrelated substances called anesthetics by the physician.

Many of the anesthetics are soluble in fats and fat-like compounds (lipoids) and likewise dissolve them. The Meyer-Overton theory of narcosis propounded a few years ago holds that there is a relation between the lipoid-solvent power of a large number of organic anesthetics and the intensity of their narcotic power; according to this the chief factor in determining the action is the coefficient of the relative solubility of the anesthetic in water and in lipoids, such as the nervous system contains in great abundance. *In other words*, for any series of fat-soluble compounds the narcotic action increases as the lipoid solubility increases and the water solubility decreases.

The view whereby this form of anesthetic action depends essentially on a modification of tissue lipoids has received wide-spread attention. There is much left undetermined thereby *with respect to* the further mechanism of anesthesia and the precise way in which alteration in the lipoid components of cells changes their irritability. Verworn, in particular, insists that anesthetics act primarily on the oxidative mechanisms of cells. It is well known that lack of oxygen usually is attended with a decrease in irritability, so that results closely resembling, if not identical with, anesthesia may be produced thereby. It is true that the rate of oxidation in active tissues may be lowered during anesthesia; but as Lillie, among others, has emphasized, this effect is rather a consequence than a cause of the lessened activity.[1] He adds that obviously whenever free oxygen is necessary to the normal activities of a tissue its withdrawal will arrest those activities; but the effects produced by lack of oxygen are not to be identified with anesthesia because of such incidental resemblances or parallelisms.

---

[1] See page 979

Even for the practical aspects of anesthesia it is of no little moment to establish the fact that tissue asphyxiation or the suppression or prevention of oxidation processes is not the essential basis of anesthesia. How then are we to regard the antistimulating action of anesthetics? How is irritability suppressed by them? A partial explanation of this is the fact, which Dr. Lillie[1] of the University of Pennsylvania has recently emphasized anew, that the primary process in stimulation is a membrane process. The permeability of cells is modified or determined by membranes. According to Lillie, anesthetics produce their essential effects by modifying the properties of the semipermeable plasma-membranes of the irritable tissues, making these structures more resistant to changes of permeability than normally. Since variations of permeability are essential to stimulation, the irritable tissue is thus rendered temporarily insensitive or irresponsive.

In recording these statements we are not giving any final solution to the varied problems of anesthesia; but the seat of action of anesthetic compounds has been more definitely located. On the view championed by Lillie the membrane is a main controlling factor in cell processes; and by changing its state, whether by lipoid-dissolving anesthetics or otherwise, we may alter the entire physiologic activity of the cell.

THE GOVERNMENT AND RADIUM

The supineness of the United States government as compared with the attitude of some foreign governments in matters relating to the health and welfare of its citizens is perhaps nowhere better illustrated than in its relation to radium. Some time ago[2] we called attention to the fact that radium deposits of unusual value had been found in Colorado, but that they had already passed to a large extent into the hands of private owners who were exporting the most valuable ore to Europe. So far the United States government has taken no steps to secure to its citizens the use of this element which, notwithstanding the exaggerated and unwarranted claims made for it by certain commercial interests, promises to have a unique field of usefulness in therapeutics. The difference in the attitude of European governments on the subject is shown by the fact stated in the editorial referred to above, that the Austrian government immediately on the discovery of radium in St. Joachimsthal secured control of the mines producing radium and arranged for its scientific and medicinal utilization.

Although possessing no radium-producing mines, Germany recently has purchased a supply of radium and placed it at the disposal of some of its university hospitals. The popularity of this action has been shown by the comments of the German press; in fact, a portion of the latter is advocating that the German government take over the entire control of the radium used for medicinal purposes in Germany. Thus the *Kölnische Volkszeitung* states that "to allow the traffic in this unique medicinal agent to be controlled by private firms is to upset all ideas of culture and humanity; a condition of affairs in which private gain and speculative interests are allowed to come into conflict with the health of the people is not to be tolerated." Yet the United States is allowing the radium found on its public domains to be monopolized by private persons without so far having made any provisions for securing to its citizens any benefit from it.

Aside from the foregoing considerations, however, a special responsibility rests on the United States to investigate not only the occurrence but also the usefulness of radium and radio-active waters, for the government itself has taken the lead in exploiting, in an entirely unjustified manner, the radio-activity of the waters of Hot Springs, Arkansas. These springs are the property of the federal government, and the latter for some time has been advertising that the waters owe their value to their radio-activity—a claim that has never been verified; in fact, the degree of the radio-activity of these waters has never, to our knowledge, been made public, although it seems that the Interior Department, which has jurisdiction over the springs, is in possession of information on this subject. The late Major Hallock, medical director of the springs, in a paper presented at the Minneapolis meeting,[3] called attention to the efforts which had been made to secure an investigation of the therapeutic value of the waters; the bill before Congress providing for such an investigation was never reported from the committee, and it is said that the failure of the committee to act on it was due to the opposition of the representatives in Congress of certain purely local interests at Hot Springs.

Thus our national government is not only allowing the deposits of what is already known to be a therapeutic agent of value to fall into the hands of private commercial interests, but also is actually a party to the exploitation of "radio-active" waters in a manner for which there is at present no justification.

THE GOUT SITUATION

It is at times decidedly discouraging to be confronted with the practical problems of the management of a long-known and widely distributed condition like gout, and to feel how inadequate our actual knowledge of it still remains. Only when we put aside all inherited beliefs and acquired prejudices and take a purely objective survey of the established facts does a wholesome realization come of the substantial progress made where chaos has seemed to reign. For the sake of this satisfaction, if nothing more, it is well to take account from time to time of the status of our established information and to gain the impetus for better results which comes from well-digested knowledge.

What are some of the accepted facts, in distinction from transitory theories, concerning gout? The fundamental one is that the gouty deposits are actually composed of salts of uric acid and that as a rule the blood of gouty subjects discloses a larger content of uric acid than does the circulating fluid of normal individuals under the same dietary regimen. It may be assumed, furthermore, that the increase in the proportion of uric acid in the blood has some bearing on the deposition of the urates. In gout there are unquestionably also certain localized tissue changes which play a decisive rôle in the precipitation phenomena at the very seat of their exhibition.

We are thus brought to the question of the possible relation of the accumulation of urates to the manifold symptoms of gout, the severe crises and characteristic "attacks." Is it true that uric acid is *per se* the instigator of these diverse manifestations? Let us frankly admit that despite the popular notions on the subject, the exaggerated pronouncements of writers like Haig, and the vague convictions of most physicians, there is no conclusive proof available to substantiate a direct pathogenic relation between uric acid and gout. It is not inconceivable that in this condition, the organism is under the influence of peculiar functional disturbances which have their outward expression in the behavior of the uric acid. Thus instead of the latter substance it might be these fundamental altered processes, themselves the occasion for the abnormal uric acid manifestations, which are the real causes of the disease disturbances set up in gout.

On the other hand, various circumstances, if nothing more, suggest a more direct relation between uric acid and the acute attacks of gout. These crises have been observed to ensue after the liberal feeding of uric acid precursors (as in sweetbreads), and after their sudden liberation in the cellular disintegrations attending the crises of pneumonia or following intensive Roentgen-ray treatment. Again, it is known that the incidence of the gouty attacks follows that of marked changes in the output of urates in the urine. The excretion is diminished before and heightened after the attack. Finally, therapeutic relief is actually obtained by the use of drugs which as a matter of fact do facilitate the excretion of urates. We can scarcely believe that all of these circumstances are to be interpreted as mere coincidences rather than as pointing to at least some causal property on the part of uric acid in the genesis of gouty conditions.

Whatever the ultimate outcome of these attempts to establish the true relation of uric acid to gout, the differences in the behavior of uric acid in the normal and the gouty organism still call for interpretation. Here, too, there is room for divergent hypothesis. It may be that the solubility of uric acid in the organism has become modified by impending conditions; or the metabolism which leads to the formation of uric acid may experience a decided upset; or the eliminating functions may be depressed by factors involving the organs of excretion, the kidneys. Each of these possibilities has been subjected to careful scrutiny and extensive investigation in the past few years. New ideas about the conditions governing solubility in solutions like the blood and tissue fluids rich in colloids have been introduced. The part played by the alkalies has been variously interpreted; but amid all the vicissitudes of theory the practical efficiency of their use has not been overthrown. As for the metabolic explanations of gout, we believe that the consensus of present opinion will point to uric acid as an end-product rather than a mere stage in purin metabolism in man.[1] Recent investigation, particularly in American laboratories, has served to emphasize new and unsuspected steps and stages in the conversion of nucleic acid compounds into the final uric acid, and to divorce purin metabolism completely from that of other nitrogenous compounds. Perhaps the kidneys themselves must assume some of the burden of responsibility for the occasional accumulation of uric acid in the blood in disease. If so, they would seem to show extreme selective action in respect to their pathologic functions.

So long as the precise nature of the metabolic upset in gout is not definitely made out, all therapeutic measures must be based in large degree on the teaching of experience. Both this and purely theoretical considerations have justified the withdrawal of uric acid precursors from the diet and the introduction of the so-called purin-free dietaries in gout. In the attempt to accomplish such changes in regimen, an exaggerated importance has now and then been given to minor details. The extreme enforcement of exclusive diets has little therapeutic justification, particularly when it offends the tastes of a sensitive patient. The ever-present debates about the relative values of white and dark meats involve at best insignificant milligrams of inconsequential distinction. Common sense is as valuable in dietetics as elsewhere. But it is as incumbent on an up-to-date physician to know what foods contain the purin precursors of uric acid and what do not, as it is to know the latest drug advertised to dispel this objectionable excretory product. So long as a further basis for therapeutic innovations is not forthcoming it is well to bear in mind not only the desirability of diminishing the production of the reputed *materia peccans*, but also of sparing the entire organism, which may be the seat of overwork from perverted processes, from undue metabolic work. This may be accomplished by reasonable moderation in the diet as a whole, by conservative physical therapy, and by a careful mode of life. As Minkowski remarked at the recent International Congress for Physiotherapy, we need not underestimate the value of purely empiric rules in the treatment of gout. But if it is admitted that there are many traditional truths in this field, we may hasten to add that there are likewise many errors sanctioned by tradition—errors which have maintained their prestige solely because they are not easily disproved.

Current Comment

THE SIGNIFICANCE OF FORMIC ACID EXCRETION

Recently we called attention to the interest which has of late been aroused in scientific laboratories in the occurrence of formic acid as a constituent of the urine.[1] Inasmuch as this substance, H.COOH, is an extreme product of oxidation carried almost to the final stage of carbon dioxid formation and can be obtained outside of the body by the oxidation of diverse materials, it requires no unreasonable assumption to postulate that it may also arise in the organism in the course of the oxidation of fats, carbohydrates or proteins. First of all, however, it is necessary to divorce facts from fancies. The prominent fact which all the more recent investigators have confirmed is the occurrence of formic acid as a usual, rather than merely a casual, component of the urine. It is found in health and diseased conditions alike; and the variations in its output have of late been studied assiduously in the hope both of correlating them with determinable pathologic processes and of learning what is the antecedent of formic acid in metabolism. In this country Dakin in particular has discussed the rôle of the compound as an intermediary stage in the catabolism of food substances and their derivatives.[2] In the earlier stages of the development of any theory the statistics of the subject are of fundamental importance. Hence it seems worth while to report the newest contributions in reference to the urinary excretion of formic acid. Dr. Strisower[3] of the First Medical Clinic in Vienna—one of the latest to undertake the study of the subject—agrees with those who believe that formic acid is a normal intermediary product of metabolism. According to him the average daily output in the urine is about 13 mg. In contrast with some of the earlier observers, Strisower has not noted any striking variations that can be attributed to specific dietary components. There are numerous diseases of the most diverse types in which the quantitive features of formic acid excretion appear to be not unlike those of normal man. In conditions attended with asphyxial symptoms, however, the output under this diminished oxidative capacity is reported to be larger than usual. The Vienna investigator agrees with several of his predecessors in noting an increased excretion in diabetes which he interprets as a sign of a disturbed metabolism of fats in this disease. Without entering into the intricate details of chemical argument we may now summarize the current opinions by the statement that formic acid may probably be an oxidative derivative of all the foodstuffs in common. Like the acetone compounds and lactic acid, for example, it is one of the simpler derivatives which "crop out" in the course of the disintegration of the larger molecules that furnish energy to our cells.

ANAPHYLAXIS AND PROTEIN DERIVATIVES

According to the most popular current theory of the genesis of the phenomena which characterize anaphylaxis, the reinjected protein or the tissue protein, as the case may be, undergoes a sort of digestive cleavage whereby toxic fragments are liberated within the organism. Vaughan and his collaborators in particular have championed the general view according to which such toxic degradation products derived from proteins initiate the symptoms of anaphylaxis. Drs. Auer and Van Slyke of the Rockefeller Institute for Medical Research have reasoned that if this explanation is tenable it ought to be possible to detect protein derivatives in those organs in which the failure to function leads to death in anaphylaxis. Accordingly, they have made chemical examinations of the lungs of guinea-pigs which exhibit a very typical permanent distention when death has occurred by anaphylactic shock. Their investigation[1] of this organ in which, according to the theory as outlined, the occurrence of protein cleavage products might be postulated, was negative in its outcome. Auer and Van Slyke point out in consequence that their experiments offer no support to the assumption that proteolytic cleavage products play an important rôle in the actual fatal serum anaphylaxis of the guinea-pig. We believe that a working hypothesis should be abandoned when facts are disclosed which are in obvious opposition to it. It would surely be unwarranted, however, to give up the very fruitful theory of Vaughan on the basis of limited negative evidence such as has just been recited.

TYPHOID FROM WATERCRESS

It is apparent that an attempt to trace typhoid infection to the use of uncooked vegetables such as lettuce, watercress and celery is likely to succeed only under rather peculiar conditions. Ordinarily the distribution of such articles of food to a large circle of consumers, and the difficulty of discovering, several weeks afterward, that such things were eaten, and by whom, are facts that conspire to render us ignorant of the real frequency of such sources of infection. A remarkable typhoid outbreak apparently due to polluted watercress has recently been reported from Philadelphia.[1] At a wedding breakfast, June 24, with forty-three guests in attendance, nineteen persons ate watercress sandwiches. Eighteen of these were ill, July 22, with typhoid fever, only two of them being in Philadelphia at the time, while the other sixteen were scattered in suburban territory and in summer resorts along the Atlantic coast as far away as Maine. Investigation by the Philadelphia Bureau of Health showed that the watercress had been secured from a farm on which the sanitary conditions were quite unsatisfactory. While the typhoid bacillus was not isolated from the cress-bed, all the other circumstances of the outbreak afford strong reason for suspecting watercress to be the vehicle of infection. It may be recalled that an outbreak of typhoid in Hackney, London, in 1903, was likewise attributed to watercress infection, although the evidence in that outbreak was not so convincing as that in the one just cited. Infection by celery has also been reported.[2] Students of epidemics will have their attention still more strongly drawn by the Philadelphia case to the possibility of infection from such sources.

THE EXCRETION OF MORPHIN

It scarcely need be emphasized that the physiologic fate of drugs employed freely in medicine deserves a most thorough investigation. To use therapeutic agents intelligently presupposes some precise knowledge of their function; and it ought also to include an understanding of what happens to them as well as to the body on which they exert their specific activities. Are they modified or destroyed in the organism? How do they or their derivatives leave it, or are they, perchance, stored up or deposited somewhere in the different tissues and organs? In the case of certain chemical substances, particularly those of inorganic matter, a partial or complete answer can already be given to such questions. In the pursuit of this information many facts of new interest have been discovered, as for example the importance of the intestine as a place for the elimination of certain elements like iron, calcium, etc. Regarding the transformation of the alkaloids in the organism, only the beginnings of an exact systematic understanding have been developed. Yet it is precisely in this group that much helpful information is to be expected. The interpretation of the peculiar phenomena of habit and tolerance in the use of some of the alkaloidal drugs presupposes exact knowledge of their fate; the problems of repeated doses involve an appreciation of possible retarded excretion and consequent cumulative action. In the case of morphin, one of the most widely used alkaloids and likewise one of the most abused, the supposition has long prevailed that it is not excreted by the kidneys to any noteworthy extent, but that in so far as it leaves the body unchanged this alkaloid is eliminated through the intestinal tract. For this reason little attention has of late been paid to the urine whenever it has, for any reason, seemed desirable to search for morphin in the organism. A careful reinvestigation of the excretion of morphin conducted at the pharmacologic institute of Heffter in Berlin[1] with more approved methods of quantitative analysis indicates that it will be necessary to revise our beliefs in this matter. As much as 39 per cent. of the morphin introduced into the body may reappear in the urine, so that evidently the participation of the kidneys in the excretion of this alkaloid is by no means negligible.

A SPECIFIC FOR CONTAGIOUS ABORTION IN CATTLE

The contagious abortion in cattle has proved to be one of the most costly diseases to which agriculture has been subjected. Methods of prevention have been under investigation for some time without great promise of eradicating the infection. What appears like a specific against the disease has been found by Dr. Taylor of the Montana Agricultural Experiment Station[2] in phenol (carbolic acid), either fed in solution or injected hypodermically. He observed that cows as a rule will eat with relish as much as 750 c.c. of a 4 per cent. solution of phenol in feed daily; but hypodermic injection as a treatment in an infected herd involves less labor than feeding. The method used with range cattle was to run them into a chute and inject 10 c.c. of 4 per cent. phenol under the skin just behind the shoulder-blade every two weeks. In cases of impending abortion, phenol can be injected in sufficient quantities to cause staggering gait and dilatation of the pupil of the eye with no apparent unsatisfactory after-effects. All males used for breeding purposes should also be treated, because the disease may be transmitted through the medium of the male unless proper precautions are observed. In human therapy we have come to adopt an attitude of extreme caution toward "specifics" for infections. What is reported in a government publication, however, as a successful procedure is entitled to receive publicity.

Medical News

COLORADO

Personal.—Dr. Leonard W. Ely, Denver, has been appointed associate professor of orthopedic surgery and Dr. Ralph W. Majors, instructor in pathology by the board of trustees in the Leland Stanford Jr. University, San Francisco.

Organization of Medical School.—At a meeting of the faculty of the University of Colorado, School of Medicine, September 1, under the new plan of organization adopted by the board of regents, the following groups were elected for the coming year: Surgery, Dr. Charles B. Lyman, chairman, and Profs. J. R. Arneill, S. G. Bonney, Cattermole, Gilbert, J. N. Hall, Moses Kleiner, Edwin J. Rothwell, Wm. H. Sharpley, Charles F. Shollenberger, Charles B. Van Zant and Herbert B. Whitney; eye, ear, nose and throat, Dr. William C. Bane, chairman, and Profs. Melville Black, John Chase, David H. Coover, Edward Jackson, John M. Foster and Robert Levy; obstetrics and gynecology, Dr. Charles S. Elder, chairman, and Profs. Thomas M. Burns, Walter A. Jayne, Francis H. McNaught and Thomas E. Taylor; specialties, Dr. George H. Stover, chairman, and Profs. Samuel B. Childs, William H. Davis, Arthur J. Markley, Newton Wiest, George E. Neuhaus,

H. T. Pershing and C. L. Pershing. The fundamentals group will be divided into two sections under Drs. Carbon Gillaspie and Washburn of Boulder, chairmen; and Profs. Burnett, Clough T. Boulder, F. Gillett, Denver; Byles, Ekeley, Mitchell, Peebles, William C. Hensen, A. R. Boulder, Emley B. Boulder, James C. Boulder, Queal, Todd and Ross C. Whitman, Denver.

ILLINOIS

Addition to Beverly Farm.—A twenty-room addition to the buildings of Beverly Farm, Godfrey, has been completed. This gives the farm a capacity for sixty-five patients.

Personal.—Dr. S. M. Wylie, Paxton, was the guest of honor at a banquet given by the members of the Bi-County (Ford-Iroquois) Medical Society at Gilman, September 4.——Dr. C. O. Molz, Murphysboro, sustained a fracture of the left shoulder and injuries of the hip by the overturning of his automobile, August 31.——Dr. E. H. Butterfield, Ottawa, for sixteen years county physician, announces his retirement from the practice of medicine.——Dr. A. S. Wall, Champaign, is reported to be ill in the Julia F. Burnham Hospital.——Dr. J. M. Evey, who has been ill in the Monmouth Hospital, is reported to be improving slowly.——Dr. W. A. Dew, Belleville, is ill with an infected wound of the hand.——Dr. S. V. Balderston, health commissioner of Evanston, has resigned.——Dr. and Mrs. Walter Hoffman, Mount Morris, have returned from Europe.——Dr. J. F. Percy, Galesburg, has returned from abroad.——Dr. and Mrs. Otis Trotter and daughter, Quincy, have returned from Europe.——Dr. and Mrs. John A. Koch, Quincy, sailed from Europe, September 20.——Dr. John E. Allaben, Rockford, has returned from abroad.

Chicago

New Officers.—Chicago Medical Women's Club, September 10: president, Dr. Effie L. Lobdell; secretary, Sadie Bay Adair.

Personal.—Dr. G. W. Torrey was exonerated by a coroner's jury September 9 after inquiries into the death of Mrs. Elizabeth Bird, who was struck by Dr. Torrey's automobile, September 3.——Dr. and Mrs. Cassius C. Rogers have returned from Europe.——Dr. Truman W. Brophy has been decorated by the French Minister of Public Instruction on account of his work on oral surgery.

KENTUCKY

Personal.—Dr. James M. Ray, Louisville, has returned from abroad.——Dr. J. D. McConnell, Shady Grove, is under treatment in a hospital in Evansville, Ind.

Extend War Against Tuberculosis.—The executive committee of the State Tuberculosis Commission met in Frankfort, September 2, and took steps toward active county campaigns to raise interest in the establishment of sanatoria for tuberculosis. It was decided to employ two men this fall, one to conduct a campaign in Henderson County and the other in Fayette County.

NEBRASKA

Personal.—Dr. Robert Percy Jensen, South Omaha, was operated on at the Omaha General Hospital, August 30, for appendicitis, and is reported to be improving.——The office of Dr. Joseph X. Campbell, Stamford, was destroyed by fire, August 27.——The residence and office of Dr. James C. Andersen, Hayes Center, was burned September 3.——Dr. Nellie Deffenbaugh, Grand Island, on September 5, assumed the superintendency of the State Tuberculosis Hospital.

Hospital Staff Selected.—Dr. John E. Summers, Omaha, chief of the staff of the Douglas County Hospital, has selected the following staff: Drs. Charles McMartin, Alfred Schalek, John W. Hellwig, Herbert C. Sumney, Arthur C. Stokes, O. T. Schultz, Alfred F. Tyler, John B. Potts, Harry L. Arnold, Alexander G. Young, Joseph M. Aiken, William H. Mick, Andrew B. Somers, Frederick J. Wearne, Rudolph Rix, Palmer Findley, Robert R. Hollister, Hugh W. Weightman, Rodney W. Bliss, William F. Milroy, Adolph Sachs, Arthur D. Dunn.

Medical School in New Home.—On November 9, the University of Nebraska School of Medicine will move from Lincoln into a new building at 42 Second Street and Dewey Avenue, Omaha. The building has been erected at a cost of $115.000 and is almost completed. The new members of the faculty coming to Omaha are: Profs. A. A. Johnson and Oscar T. Schultz from Western Reserve University, Cleveland; Prof. Claude R. Michell, physiology; Prof. C. W. M. Poynter, Lincoln, anatomy; Prof. A. E. Gunther, physiology and pharmacology; Prof. Irving S. Cutter, Lincoln, biologic chemistry and director of laboratory work, and Prof. W. A. Willard, the microscope. The following additions have been made to the clinical staff: Dr. John E. Summers, surgery; Drs. Ray Crummer, Omaha, and E. L. Bridges, Omaha, medicine, and Dr. J. P. Lord, Omaha, orthopedic surgery.

NEW YORK

New York City

Railroad Accidents Increase.—The report of the Public Service Commission shows that for the month of July there were 29 deaths from railroad and street railways in New York City, exactly the same number as for the corresponding time of last year. There were 197 persons seriously injured. Altogether there occurred during the month of July 7,884 accidents of various kinds, including 310 persons struck by cars, 1,152 vehicles struck by cars and 320 derailments.

Death-Rate in Hospitals Increases.—The report of the Health Department for the week ending September 13 shows a marked increase in the number of deaths in the hospitals of the city compared with a similar period of last year, but a corresponding decrease in the number of deaths in the tenements. This is interpreted as indicating that the people are coming to appreciate the benefits of hospital care. The total death-rate of the city for the week under consideration was 12.17, as compared with 12.39 for the corresponding week of 1912. There was an increase in the number of deaths from Bright's disease and heart diseases, while there was a marked decrease in the number of deaths from pulmonary tuberculosis.

PENNSYLVANIA

Scarlet Fever Closes Schools.—Owing to thirty cases of scarlet fever in the Sugar Notch Borough, the schools have been closed and the town practically quarantined.

Reading Fight Tuberculosis.—Through the efforts of Miss Mary Parvin, the school lecturer of the Reading Tuberculosis Society, a message on school and home hygiene has been delivered to thousands of children and transmitted by them to their parents. Talks are given to children in the sixth, seventh and eighth grades and the question method is used.

Philadelphia

Grand Jury to Investigate Dumping of Garbage.—The Federal Grand Jury convened on September 15, to probe the dumping of garbage in the Schuylkill River. Jacob L. Havener, Jr., superintendent of the American Product Company, has been held under $800 bail for court by Commissioner Edmunds, in the federal building, on a charge of having dumped refuse into a navigable stream. The minimum penalty for the offense charged is a fine of $500 or thirty days imprisonment, or a maximum penalty is $2,500 fine and one year imprisonment.

School for Cripples Opens.—The special school for cripples in the Horace Binney annex of the McCall School at Sixth and Spruce Streets opened September 11, and a bus made the rounds of the section of the city between Christian and Lehigh Avenue and Broad Street and the Delaware. Everything that will contribute to the comfort and safety of the children has been arranged. The classroom is directly at the entrance of the building, their classes will be dismissed fifteen minutes early and at noon they will be served with penny lunches by the Starr Garden Association.

Dental Dispensaries Have Additional Surgeons.—Director Neff of the Department of Public Health and Charities, has appointed the following dental physicians to have charge of the two additional dental dispensaries that have been established for the benefit of public schoolchildren: Drs. Louise Schembs, Louis Jacobs, Armin T. Fellows and Edward K. McPherson. The successful candidates were the first four on the civil service eligible list for such positions, which pay $700 each. The new dispensaries will be established at the Thomas May Pierce School at Twenty-Third and Cambria Streets, and at the William B. Hanna School at Fifty-Eighth and Media Avenue.

To Sterilize All Water for Public Schools.—Sterilization of drinking water in the public schools, especially in the district east of Broad Street and south of Allegheny Avenue, is planned by Dr. Walter Cornell, chief medical inspector of the public schools, to guard against further spread of typhoid fever among schoolchildren. By an investigation and survey made last June by Dr. Samuel G. Dixon, State Health Commissioner, it was learned that the majority of victims of typhoid fever were among the schoolchildren. The number of new cases of typhoid reported to the Bureau of Health during the week ending September 13, was 71 as compared with 47 for the week previous.

New Institutions Authorized.—The wise initiative of the medical profession of Philadelphia and Pennsylvania has finally brought into legal existence large new institutions that will bring the city and state well into the advance along social lines: Mentally defective women of childbearing age, of whom at least 15,000 are known to be within the state, will now be permanently segregated in a great farm colony in a remote mountain forest reserve, thus preventing further multiplication. A home for alcohol and drug habitués, long agitated, is provided for in another forest reserve as, elsewhere, is an industrial home for women. Not "paths" of any kind or Christian Scientists or other self-seekers but everyday doctors are the plodders who thus work for and aid the public, just as in all other great social movements.

TEXAS

New Building for Sanitarium.—The Texas Baptist Memorial Sanitarium, Dallas, has called for bids for the erection of an additional building, 40 by 90 feet, two stories in height, of fireproof construction, to cost about $15,000.

Inspection at Mexican Ports.—As the result of a conference with Dr. Ralph Steiner, Austin, state health officer, acting state quarantine officer Dr. E. S. McCain, Galveston, has proceeded to Tampeco, Mex., to take charge of the inspection of Americans desiring to leave that country.

New Hospital Building.—The State Medical College, Galveston, is to erect a nurses' home for which $65,000 was appropriated by the last legislature. As the result of this, the fund of Mrs. R. Waverly Smith and John Sealy, Galveston, of $80,000 for a new building for the John Sealy Hospital for white women patients, becomes available.

Free Clinic Opened.—The Physicians' Free Clinic Association opened a clinic at 211 Commerce Street, Fort Worth, September 1. The following physicians are members of the staff: Drs. W. M. Trimble, Eugene Hall, O. L. Jones, Webb Walker, E. C. Axtell, P. L. Hooper, D. C. Rumph, T. G. Rumph, Ross Trigg, F. G. Sheddan, H. O. Brannan, J. T. Montgomery, J. L. Cooper, Wallace B. Smith, C. F. Hayes, J. W. Kuykendall, J. D. Mitchell, R. O. Braswell, Alden Coffey, J. H. McLean, E. L. Myrick, R. H. Gough, C. H. Pember, Crittenden Joyes, S. J. Brownson, G. E. La Beaume, W. D. Littler, John Potts, F. E. Rushing, M. E. Tadlock, W. C. Rountree, G. T. Allison, A. R. Hays, Field Farrar, C. E. Waller, J. T. Edwards, C. A. Ward and Nugent brothers. Dr. R. H. Goff has been elected president of the clinic; Drs. Field Farrar and D. C. Rumph, vice-presidents, and Dr. J. L. Cooper, secretary-treasurer.

Personal.—Dr. Henry Hartman, assistant health officer and bacteriologist, Austin, has resigned to accept a position as head of the pathologic department of the University of Texas, Galveston.——Dr. Z. F. Lillard, has been elected a member of the Board of Health of Houston, vice Dr. John T. Moore, resigned. ——Dr. William M. Moore, Paris, was operated on at the Aiken Hospital, September 3.——Dr. I. L. McGlasson, state quarantine officer, Galveston, has returned from abroad.——Dr. Joe Shelton, Waco, has been appointed chief surgeon of the St. Louis, Brownsville and Mexico Railway Company with headquarters at Corpus Christi.——Dr. C. H. McCollum, Hico, has gone abroad.——Dr. T. T. Jackson, San Antonio, has been appointed a member of the State Board of Health, vice Dr. A. A. Ely, Galveston, recently appointed a member of the board of regents of the University of Texas.——Dr. R. W. Noble, Temple, fractured his left arm while cranking his automobile, recently.——Dr. W. H. Betts, Fort Worth, was attacked by a patient and seriously injured, recently.

CANADA

Provincial Reciprocity with Great Britain.—Reciprocity in medical licenses has now been in force for some time between Great Britain and the following three Canadian provinces, Nova Scotia, Quebec and Prince Edward Island. New Brunswick is the latest province to join in this arrangement and it will very shortly be put into force.

Provincial Medical Board of Nova Scotia.—At the recent annual meeting of the Provincial Medical Board of Nova Scotia, a resolution was passed agreeing to accept the registration certificate of the registrar of the Medical Council of Canada, and without further examination, will register the holder thereof, on furnishing proof of identity and paying the necessary provincial registration fee. At the same time the board passed a resolution deprecating the fact that one province, British Columbia, on account of existing local legislation is unable to accord the same general recognition to all holders of the Dominion Medical Council's certificate. During the past year there were ten additions to the register of Nova Scotia and ten erasures on account of death, leaving the numerical strength of the register of that province as it was at 671. Of this number only about 440 are residents in Nova Scotia, the remaining number being chiefly in the United States. Dr. John Stewart, Halifax, was reelected president, and Dr. A. W. H. Lindsay, Halifax, registrar.

Hospital News.—From the leper hospital at Tracadie, N. B., two patients have recently been discharged. One man aged 39 left a year ago after having received twenty injections of nastin. Two subsequent examinations show him remaining well. The other was a man of 67 years, discharged in November last. He had received sixty injections in all and remains in good health. The physician now in charge of this government institution is Dr. Langis.——Prince Edward Island is to have a tuberculosis sanatorium through the generosity of the Hon. Charles Dalton. Dr. A. F. Miller, superintendent of the Kentville, N. S. sanatorium, will assist in selecting site and erection of building.——Three new wings are being added to the Children's Memorial Hospital, Montreal.——The provincial hospital for the insane at Battleford, Saskatchewan, is nearly completed. Dr. J. W. McNeil, Hanley, Sask., is to be the superintendent.——The Dominion Government is building a hospital and school for Indians at The Pas, at a cost of $76,000.——A hospital is to be built at Comox, B. C., by the Sisters of St. Joseph.

LONDON LETTER

(From Our Regular Correspondent)

London, Sept. 6, 1913.

The Investigation of Pellagra

Dr. Louis Sambon, who was twice sent to Italy by the pellagra investigation committee, has now gone on a third expedition to study the disease in America and the West Indies. In the United States he will meet Dr. Stiles and others who have devoted themselves to the study in that country. The cause of pellagra was long held to be due to the consumption of damaged maize, since it is in maize-eating countries that it prevails; but Dr. Sambon's theory, which is based on carefully thought-out epidemiologic grounds, is that pellagra, like malaria, yellow fever, filariasis, etc., is conveyed by an insect—a simulium, or sand-fly. It is owing to Dr. Sambon's untiring advocacy of this view and his examination of cases that the disease has now been recognized in England. The first case dates back only to October, 1912, but already other cases are being recorded in the medical journals, sometimes two or three in one number.

Unhealthy Offices for Clerks: Proposals for Betterment

The health officer for the City of London, Dr. Collingridge, states in his recent annual report that many clerks have to work in unhealthy surroundings, and that legislation is necessary for the improvement of the conditions of their employment. He refers to the Railway Offices Bill as a step in the right direction, but says that it is difficult to understand why provisions for efficient ventilation and adequate lighting should be restricted to railway offices. Two other bills dealing with the conditions of employment of all clerks have, however, been before Parliament for the last two sessions. One of them, the Factory and Workshops Bill, which was first introduced in the House of Lords by Lord Salisbury in 1912, proposes to bring underground workshops and offices under the jurisdiction of the Factories Acts, so that they may be inspected under the same terms and subject to the same penalties as large factories and workshops. This bill is supported by the National Federation of Shop-Workers and Clerks, which has a membership of 140,000. Last session it passed through all the stages in the House of Lords, but no progress could be made with it in the House of Commons owing to pressure of government business. The National Union of Clerks, while supporting Lord Salisbury's bill, has also had before Parliament for three years a measure of its own, the Offices Regulation Bill, which seeks to bring all persons employed as clerks in offices under the protection of the Factories Acts. It is stated that thousands of clerks are compelled to work not only in unhealthy underground offices but in offices just as insanitary which look out on courtyards. It is also stated that a factory inspector has frequently to pass through inadequately ventilated and lighted rooms, where clerks are employed, on his way to the workshop which he is to inspect, and yet he is powerless to call attention to the unhealthy condition of these premises. The mortality of clerks from diseases of the chest is twice as high as among the general population. Twenty-five per cent. of the deaths are due to consumption, and 33 per cent. to some form of lung disease. This excessive death-rate is ascribed partly to the sedentary nature of clerical employment, and partly to the dirt and dust, the cold in winter and the heat in summer, of the offices in which many ot these clerks have to work.

New Buildings of the London School of Tropical Medicine

As the result of the appeal of Mr. Austin Chamberlain, formerly Secretary for the Colonies, considerable additions have been made to the London School of Tropical Medicine. The funds have been partly subscribed by the public and partly granted by the government. Additional buildings have been erected, consisting of a laboratory providing accommodation for sixty students, and of a hostel with provision for twenty-five residents. The new laboratory has been built so as to be continuous with the old laboratory of the school. It is a square single-story building, lighted by a weaver-roof. The accommodation set free by it has rendered possible the formation of several special laboratories, of preparation rooms, of the director's room and of incubation rooms. The resident accommodation is intended for the use of students qualifying for appointments in connection with the Colonial Office, but it is expected to be sufficient to enable any of those attending the school, who desire, to reside on the spot. Each of the rooms is furnished as a bed-sitting room, and as a result of the extensions there is now considerably more space available for the common rooms connected with the school. In connection with the work of the school an important new departure has been made by the inauguration of a course in Tropical Sanitation and Hygiene, this step having been taken in consequence of a demand expressed from India and from most of the dominions. It is to consist of an eight weeks' course of laboratory studies and part health work, special attention being given to bacteriology and hygiene.

Impure Milk

The report just issued by Dr. Collingridge, health officer of the City of London, is not reassuring as to the quality of our milk-supply. From 1902 onward samples of the milk arriving at the railway termini have been systematically taken and submitted to bacteriologic examination by Dr. F. W. Andrews. He found that of these samples 20 per cent. were dirty, 46.6 per cent. were "fairly clean," and only 33.3 per cent. were describable as "clean." The tubercle bacillus was present in 6.6 per cent. of the cases. A study of the returns from 1904 to 1912 shows that the proportions between "fairly clean" and "unclean" have fluctuated very widely—in one year being as 80 to 12, and in a later year 28 to 71. In only one year were all samples examined found free from tubercle bacilli. These results indicate the prevalence of highly unsatisfactory conditions in the milk trade. Dr. Andrews says that until the hands of farmers, dairymen and others engaged in the distribution of this indispensable commodity are forced by statute no real or lasting improvement can be looked for. Indeed, it is evident that the inspection of dairies and cowsheds is not of itself enough, though even there much is to be done. The old pattern of churn in which the milk was sent by rail has been improved. The perforations that were provided in intention for ventilation, but in effect for the admission of dirt, have been done away with, and replaced by dust-proof cans; but that improvement must be neutralized as long as there is no guarantee that the touch of those engaged in the processes of dairying is free from contamination.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Sept. 1, 1913.

Annual Meeting of French-Speaking Alienists and Neurologists

This congress was held at Le Puy, August 1 to 7, under the presidency of Dr. Arnaud of Vanves and the vice-presidency of *agrégé* Professor Dupré of Paris. Three questions were discussed: first, the disturbances of motion in dementia praecox; second, anesthesias in cerebral hemiplegia; third, the therapeutic and medicolegal indications for operation on the insane. Dr. Lucien Picqué, surgeon of the hospitals of Paris, read a paper on this subject, an interesting discussion following.

OPERATIVE INDICATIONS IN THE INSANE

Dr. Picqué remarked that half a century ago the action of surgery on mental disturbances was regarded from widely different points of view. Some operated directly on the brain or its envelopes, but their attempts are still too few and too uncertain to furnish the basis of a rational surgery. Other surgeons, and these are the more numerous, attempt to cure certain forms of insanity by the surgical treatment of pathologic foci situated outside of the brain. Numerous "cures" have been announced from such procedures. Picqué reports a total of 2,666 operations in his service at the Sainte-Anne asylum up to Jan. 1, 1913. This includes 314 organic psychoses and 383 congenital psychoses—altogether 697 patients —on whom he has performed operations of urgency. There remained 1,969 patients on whom surgery has given variable results. Picqué believes that at present it is necessary to beware of operative statistics based on doubtful facts, and in the first place to establish the rôle of extracerebral pathologic foci with respect to the origin of insanity; that is, to define the nature of the relations between an organic lesion and certain concomitant mental conditions. This problem is at the base of the question of operative indications in the insane. To-day the study of certain functions permits the definition of the rôle of organic lesions in the production of mental troubles, as in the case of the relation between the thyroid gland and certain forms of insanity. It has been known for a long time also that infections of the liver or the kidneys may give rise to mental troubles. The importance hitherto given to hereditary influences has waned without disappearing. A surgeon, on the one hand, should take heredity into consideration so that he may recognize patients whose mental condition constitutes a contra-indication to operation. On the other hand, the theory of the extracerebral origin of certain mental disturbances permits the surgeon to attack the latter in their peripheral foci. The coincidence of insanity and a peripheral lesion, however, does not imply a causal connection.

When the therapeutic indication has been established it is necessary to decide on the therapeutic method to be employed. Some cases of insanity may, after a perfectly justified operation, persist, become aggravated or be cured according to the method of treatment employed. The surgeon's method should be chosen with reference to the mental condition of the patient, and thus questions of surgical technic play an important rôle in psychiatry. Because of its difficulties surgery of the insane constitutes a special branch which Picqué calls "surgical psychotherapeutics." It calls for a long apprenticeship and, it is needless to say, for high moral qualities.

While the insane patient is considered to-day as a sick man who has the right to benefit by all the resources of medical and surgical therapeutics, the French law of 1838 contains nothing which authorizes the surgeon to give surgical relief to the insane as a matter of course. The request for authorization from the families of the insane gives rise to great abuse.

Dr. Lagriffe of Auxerre remarked that the surgery of the insane was beset with great difficulties, "the surgeon's knife often turning against himself." He cited the case of a patient who complained of various vague disturbances in the genital region, and who persuaded a skilful surgeon to operate on a by no means troublesome varicocele. The surgeon performed the operation, which was neither useful nor necessary, merely to satisfy the patient. The vague troubles did not cease. The patient pursued the surgeon first with complaints and then with reproaches and finally made an unsuccessful attempt to kill him.

Professors Régis of Bordeaux and Gilbert Ballet of Paris, with Drs. Dupré and Dide of Toulouse, united in depreciating the rôle of surgery in alleged cures of mental disease, which they were inclined to attribute to spontaneous recovery in most cases.

In his reply, Dr. Picqué, while agreeing with the criticisms made on the possible abuses of the surgery of the insane, remarked that these abuses could *not* be regarded as an argument against such surgery itself.

REVISION OF THE LAW WITH REGARD TO THE INSANE

On the motion of Prof. Gilbert Ballet, the congress unanimously protested against the proposed revision of the law of 1838, now before the senate (The Journal, May 31, 1913, p 1719), and especially against the clause requiring judicial procedure before patients are admitted to asylums or sanatoriums. If it is legitimate and desirable to require a judicial decision in the case of the criminal insane and those who formally protest against being placed in asylums, it would be useless and vexatious to impose such a requirement on other patients who constitute more than 80 per cent. and thus to transform asylums and sanatoriums into prisons, entered only after court procedure.

ORGANIZATION OF INTERNATIONAL CONGRESS OF NEUROLOGISTS, PSYCHIATRISTS AND PSYCHOLOGISTS

The congress passed a resolution looking toward the formation of an international committee to organize an international congress of neurologists, psychiatrists and psychologists.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Aug. 29, 1913.

Personal

Professor Rieder Pasha died in Bonn, August 29, at the age of 51 years. In 1895 he was assistant to Schede of Bonn, the well-known surgeon, and in 1898 he was called to Turkey as the inspector of the Turkish Medical School for Army Physicians in order to organize this after the German method. He filled his position capably and an account of his work was published with the favorable comment of his early teacher. Schede later had a chance to show his great interest in his pupil. In 1905, Rieder, while going through a new building for the military medical school, which he founded, fell several stories and injured his spine so that it was feared that the injury might be fatal. Schede himself hastened at once to Constantinople and had the good fortune to save Rieder's life, but the latter remained a cripple. His usefulness for Turkey was naturally over and in 1905 he returned to Bonn. There he again took up his work as teacher in the university and became the director of the surgical section of the hospital. The various difficulties with which he had to struggle are described in his book on the work which he did in Turkey.

Professor Neuberg, who for many years has been assistant to Professor Salkowski, has been appointed a demonstrator in the chemistry division of the Kaiser Wilhelm Institute for Experimental Therapy in Dahlem, near Berlin, with the approval of the kaiser.

Women Students in the German Universities

In the twenty-one German universities during the last summer, out of a total number of 60,000 students, 3,436 were women, the highest number that the women students had attained up to this time. Counting such students as attended only a small number of semesters or only a few lectures and did not take the examinations, more than a thousand women attended. The number of women medical students was 790. Most of the women attended the Prussian schools, only 20 per cent. being in Berlin.

A Further Decrease in the Birth-Rate in Prussia

In the first quarter of 1913 the number of births in Prussia was 293,652, which shows a decrease as compared with the same quarter of 1912 of about 10,000, or 3.56 per cent. The country is more concerned in this decrease than the city, but at the same time there were more births in the country proportionately to the general population than in the cities. There were 25.32 births per thousand inhabitants in the cities, while in the country there were 31.4. The number of deaths also has decreased proportionately. There were 162,871 as against 175,818 in the previous year, a decrease of 12,974, or 7.4 per cent. There was thus an increase in the population of about 3,000 over the first quarter of 1912. Of great importance was the decrease in the death of infants, which dropped from 43,721 to 40,440. There were 5,000 less deaths due to contagious diseases than in the first quarter of 1912. As illustrative of the value of the struggle against tuberculosis, there was a decrease in the number of deaths from this disease of 1,700. The suicides increased heavily, from 1,760 to 1,989; also the murders, from 3,672 to 3,945. Marriages also increased. They reached a total of 64,284, that is, 1,500, or 2.61 per cent., more than in the previous year.

Completion of the Plans for Care of Pulmonary Diseases

Toward the completion of the proposed program for the care of pulmonary diseases in Germany, the German Central Committee for the Care of Tuberculosis has named a commission with an auxiliary under the direction of the directors of the Robert Koch Institute, Dr. Gaffky and the directors of the German national insurance body. They are to arrange for a closer union between the 1,500 various German institutions. For the same purpose the *Journal for the Care of the Tuberculous*, published under the direction of the general secretaries, Professor Nietner and Professor A. Kayserling, has arranged to issue 12,000 copies in which will be contained the various regulations of the organizations interested in the care of tuberculosis.

BUDAPEST LETTER

(From Our Occasional Correspondent)

Budapest, August 30, 1913.

Title for Court Physician

Dr. Kerzl, court physician, has had conferred on him the title of "Special Medical Privy Councilor" by His Majesty, Francis Joseph. This is the first time that this title has been conferred here on a medical man. The special appointment is largely due to the personal friendship which His Majesty bears toward his body physician. Among other things this is also shown by the implicit obedience with which the king follows the instructions of Dr. Kerzl. No matter what important meeting or function may be scheduled, if Kerzl advises His Majesty to remain indoors he always obeys, although it is generally known that it is most disagreeable to the king to remain indoors even for twenty-four hours.

Cholera in Hungary

What has been particularly dreaded by medical men of Hungary ever since the outbreak of the Balkan war has at last come to pass: Cholera has spread beyond the borders of the Balkan countries and sporadic cases have been brought into Hungary by soldiers retiring from the Bosnian service. Nominally since the occupation of Bosnia by Austria-Hungary, soldiers recruited in Bosnia are sent to serve in Austria-Hungarian regiments and reversedly Austro-Hungarian soldiers are sent down to Bosnia. This has been done from a strategic point of view. Since the first half of August Bosnian regiments have been kept in readiness and even reservists have been summoned in extremely large numbers. These reservists have been discharged from service in the last two weeks and although the strictest precautions were taken, yet they have brought cholera into Hungary. The number of cases reported as yet is only six or seven, and in view of the stringent regulations, which are observed not only by medical men but also by lay people in the reporting of cases, it is very probable that the spread of cholera will be checked. Soldiers coming back from Bosnia after a long and severe service, instead of being kept under observation for a few days at the Hungarian border, have escaped. To prevent this the minister of war has ordered that soldiers escaping medical observation will be regarded as deserters, the penalty for which is a punishment service of one or two years.

Marriages

Viola L. Pennypacker, M.D., Huntington, W. Va., and Mr. William H. Scanland, Jr., of Benton, La., at Jenkintown, Pa., June 26.

Harry Raymond Mutchler, M.D., Rockaway, N. J., to Miss Helen Alene Van Cleaf of Asbury Park, N. J., June 25.

Joseph Edward Brookshire, M.D., Nowata, Okla., to Miss Anna C. Steward of Glenwood Springs, Colo., August 23.

Rudolph F. Rohlfing, M.D., Colorado Springs, Colo., to Miss Cora Ethel Luke, at Sheridan, Wyo., August 14.

Alfred Stahl, M.D., Newark, N. J., to Miss Martha Lowe of Mendham, N. J., September 3.

John Munn Hanford, M.D., to Miss Gwendolen Smith, both of New York City, September 3.

J. B. Chaiken, M.D., to Miss Jeannette G. Kirkel, both of Philadelphia, September 7.

Edwin Stanley Cooke, M.D., to Miss Anna Barrett, both of Philadelphia, September 1.

Nazareth A. Jerijian, M.D., to Miss Semagule Doodakyan, both of Chicago, August 30.

George Ives, M.D., to Miss Vivian Loretta Trentle, both of St. Louis, August 18.

Ben Vaughan, M.D., to Miss Mamie Agnes Decker, both of Louisville, September 1.

Deaths

Theodore S. E. Schaepkens van Riempst, M.D. University of Ghent, Belgium, 1900; of New York City; a member of the Medical Society of the State of New York; for four years surgeon to the Red Star Line; a member of the staff of the Polyclinic Hospital and Demilt and Hudson Street dispensaries and later chief of clinic of the outpatient department of St. Luke's Hospital and lecturer in genito-urinary surgery at the Polyclinic Hospital; a member of the American Urological Association; was accidentally drowned in Saranac Lake while fishing, August 21.

John Milton Bigelow, M.D. College of Physicians and Surgeons, New York City, 1870; A.B., A.M. and Ph.D. (Hon.), Williams College; a fellow of the American Medical Association; professor emeritus of materia medica, therapeutics and diseases of the throat and nose in Albany (N. Y.) Medical College; at one time president of the Albany County Medical Society and honorary president of the Pan-American Medical Congress; attending physician at the Albany and St. Peter's Hospitals; died at his home in Albany, August 25, aged 67.

Sinkler Nicholas Latham, M.D. Birmingham (Ala.) Medical College, 1897; a fellow of the American Medical Association; formerly chief surgeon of the Sloss-Sheffield Steel and Iron Company; later chief surgeon of the Birmingham Coal and Iron Company at Mulga; division surgeon for the Southern Railway with headquarters at Birmingham; died in a sanatorium in Birmingham, August 31, from nephritis, aged 40.

Joseph Beggs Carter, M.D. Rush Medical College, 1882; a member of the Kansas Medical Society; for eighteen years a member of the Kansas State Board of Health and once chairman of the board; for several years physician of Fort Scott and Bourbon County, and local surgeon for the Frisco and Missouri Pacific Systems; died at his home in Fort Scott, September 2, from nephritis, aged 54.

Elisha Merritt Whitten, M.D. Medical School of Maine at Bowdoin College, Brunswick, 1865; twice president of the Nebraska State Medical Association and at one time professor of gynecology in the University of Nebraska Medical College; a practitioner of Nebraska City for 48 years; died at his home, September 4, from disease of the heart and kidneys, aged 76.

Thomas Edward Pickett, M.D. University of Pennsylvania, 1865; a fellow of the American Medical Association; surgeon in the Army throughout the Civil War; a member of the American Academy of Medicine and a life member of the British Association for the Advancement of Science; died at his home in Maysville, Ky., September 3, from senile debility, aged 72.

Walter E. Russell, M.D. Hahnemann Medical College, Chicago, 1889; a fellow of the American Medical Association; for several terms city health officer and a member of the School Board of Walla Walla; who underwent operation a few weeks ago on account of malignant disease; died at his home in Walla Walla, August 28, from carcinoma, aged 55.

Frank J. Wagenseller, M.D. University of Pennsylvania, Philadelphia, 1878; a member of the Medical Society of the State of Pennsylvania; county inspector for Snyder County for the State Board of Health; a practitioner of Selinsgrove, Pa.; died in the Samaritan Hospital, September 5, from uremia, two weeks after a surgical operation, aged 57.

Edwin Rushton Boden, M.D. Long Island College Hospital, Brooklyn, 1880; at one time a member of the common council of Oneida, N. Y.; for fourteen years deputy collector or cashier in the Internal Revenue Service; died at his home in Oneida, August 16, from cerebral hemorrhage, aged 54.

Howard Smith, M.D. University of Pennsylvania, 1871; surgeon, lieutenant, U. S. Navy, retired in 1890 for incapacity resulting from incident of service; assigned to active duty during the war with Spain; died in the Naval Hospital, Norfolk, Va., September 4, aged 65.

Theophilus H. Andress, M.D. College of Physicians and Surgeons, New York City, 1864; a veteran of the Civil War, in which he served as a medical cadet; a practitioner of Sparta, N. J., for nearly half a century; died at his home, August 26, aged 72.

Henry M. Emerick, M.D. College of Physicians and Surgeons, Baltimore, 1880; a member of the Medical Society of the State of Pennsylvania; died at his home in Milton, August 31, from acute indigestion, aged 59.

John Lochner, M.D. New York University, New York City, 1871; for nineteen years a member of the Jersey City Board of Health; for twenty years medical examiner for the Jersey City Fire Department, and for seventeen years city physician; consulting physician to the Home for the Homeless; died at his home in Jersey City, September 3, aged 68.

Samuel Rozier Catts, M.D. Baltimore Medical College, 1906; a fellow of the American Medical Association; for several years a member of the Medical Corps of the Army, and at one time on duty at the National Soldiers' Home, Hampton, Va.; died at the home of his father in Alexandria, Va., August 29, from tuberculosis, aged 36.

Charles W. Maddox, M.D. Louisville (Ky.) Medical College, 1894; a fellow of the American Medical Association; local surgeon in Longton, Kan., for the Santa Fe System; a member of the Atchison, Topeka & Santa Fe Railway Association of Physicians and Surgeons; died at his home in Longton, August 20, aged 41.

Ellwood Maulsby Corson, M.D. University of Pennsylvania, Philadelphia, 1863; a fellow of the American Medical Association; acting assistant surgeon and assistant surgeon in the Navy during the Civil War; for more than 40 years a practitioner of Norristown, Pa.; died at his home, about September 7, aged 71.

George Angel Edwards, M.D. College of Physicians and Surgeons, New York City, 1877; a fellow of the American Medical Association and a well-known gynecologist of Syracuse, N. Y.; died in St. Joseph's Hospital, September 3, a day after a surgical operation, aged 68.

Philander Sumner Boyd, M.D. University of Tennessee, Nashville, 1888; a member of the Medical Association of the State of Alabama, and for about twenty years a practitioner of Florence; died in New York City, August 30, from disease of the stomach, aged 63.

John Thomas Broughton, M.D. University of Pennsylvania, Philadelphia, 1853; a member of the Medical Association of the State of Alabama and a pioneer practitioner of Butler County; died at his home in Greenville, August 29, from heart disease, aged 83.

George Y. Pierce, M.D. Southern Medical College, Atlanta, 1890; for several terms a member of the Common Council and a member of the Board of Education of Atlanta, and at one time a member of the Board of Health; died at his home, August 25, aged 49.

Charles Edward Keeler, M.D. College of Physicians and Surgeons, Keokuk, Iowa, 1879; local surgeon at Lake Mills, Iowa, for the Chicago and North-Western Railway and health officer of Lake Mills; died at his home, August 23, from tuberculosis, aged 59.

Charles Herman Reinsberg, M.D. College of Physicians and Surgeons, New York City, 1900; a graduate both in theology and medicine and a clergyman of the Protestant Episcopal Church; died at his home in New York City, August 27, aged 46.

William H. Busch, M.D. Northwestern Ohio Medical College, Toledo, 1888; for several years infirmary physician of Erie County, Ohio, and later county health officer; died at his home in Sandusky, August 22, from malignant disease, aged 49.

Allison Emery Drake, M.D. University of Denver (Colo.), 1901; at one time professor of foreign languages in Westminster University; for sixteen years a resident of Denver; died in Park Avenue Hospital in that city, August 28, aged 53.

John P. Pardue, M.D. Missouri Medical College, St. Louis, 1880; formerly professor of materia medica and hygiene in the St. Louis College of Physicians and Surgeons; died at his home in St. Louis, August 29, from nephritis, aged 61.

Alexander M. Troup, M.D. University of Buffalo, N. Y., 1900; while answering a sick call a few miles from his home in Holland, N. Y., August 24, was pinned under the seat of his overturned automobile and instantly killed, aged 35.

George T. Wrennick (license, Indiana); for nearly fifty years a practitioner of the state, Philadelphia; a veteran of the Civil War; died at the home of his son in Brazil, August 29.

Henry Janss, M.D. Kentucky School of Medicine, Louisville, 1893; died at his home in Springfield, Mo., August 31, from cerebral hemorrhage, following heat prostration, aged 52.

N. S. Grice (license, Twentieth Judicial District Board, Texas, 1891); died suddenly at his home in Bryan, August 6, from heart disease, aged 58.

Henry Cushman Turner, M.D. New York University, New York City, 1867; of Brooklyn, consulting physician to the Norwegian Hospital; died at the home of his brother in Washington, Conn., August 16, from nephritis, aged 68.

Charles P. Spottswood, M.D. Minnesota Hospital Medical College, Minneapolis, 1888; founder and surgeon-in-chief of the Hankinson (N. Dak.) Hospital and local surgeon of the Soo Line; died in Minneapolis, August 11, aged 49.

George W. Walworth, M.D. Starling Medical College, Columbus, Ohio, 1891; a member of the Michigan State Medical Society; of Reese; who had gone to Rochester, Minn., for a surgical operation; died recently from pneumonia.

Arba Reed Green, M.D. New York Homeopathic Medical College, 1880; pediatrist to the Albany Homeopathic Hospital; from 1871 to 1881 coroner of Rensselaer County, N. Y.; died at his home in Troy, September 1, aged 59.

Harry Murrell Carter, Jr., M.D. Tulane University, New Orleans, 1911; superintendent and proprietor of the Carter Sanatorium, Tucson, Ariz.; died at his home in that city, August 28, from tuberculosis, aged 23.

James Edward M. Lordly, M.D. College of Physicians and Surgeons, New York City, 1868; of New York City; president of the St. George Club of New York; died at his summer home in Chester, N. S., August 21, aged 68 .

Bernard W. Slagle, M.D. University of Pennsylvania, Philadelphia, 1877; of Smith Center, Kan.; while waiting at a station to take a train for Colorado, about August 24, died suddenly from cerebral hemorrhage.

Daniel Aloysius Shay, M.D. Baltimore University, 1901; New York University, New York City, 1904; a practitioner of Brooklyn for ten years; died in Marlborough, N. Y., August 21, from acute nephritis, aged 37.

Frederick Stanton McKinney, M.D. Marion-Sims College of Medicine, St. Louis, 1898; formerly of Leetonia, Ohio, but for a few months a resident of St. Louis; died suddenly in Leetonia, August 19, aged 41.

Margaret S. McNiff, M.D. Hahnemann Medical College, Chicago, 1893; formerly professor of obstetrics in Hering Medical College; died at her home in Chicago, August 21, from heart disease, aged 63.

Theodore Robert Miller, M.D. New York University, New York City, 1886; for seven years chief physician to the City Home, Marshalsea; died at his home in Pittsburgh, September 1, aged 53.

R. Wallace Salisbury, M.D. Chicago Homeopathic Medical College, 1886; formerly a member of the Iowa State Medical Society; died at his home in Estherville, about August 14, aged 53.

Jacob Derx, M.D. State University of Iowa, College of Homeopathic Medicine, Iowa City, 1887; of Kansas City, Mo.; died in Bethany Hospital, Kansas City, Kan., August 8, aged 74.

Elias L. Dagley, M.D. University of Louisville, Ky., 1887; for eighteen years a resident of Oklahoma; died in his apartment in Oklahoma City, August 17, from heart disease, aged 69.

Lucien Fletcher Webb, M.D. Detroit Homeopathic College, 1904; a member of the staff of Grace Hospital, Detroit; died at his home, September 3, from typhoid fever, aged 35.

Charles Patten Clark, M.D. University of Toronto, Ont., 1889; of Buffalo; died suddenly from heart disease while driving his automobile in Buffalo, August 28, aged 49.

Annette H. Waggoner, M.D. University of Iowa, College of Homeopathic Medicine, Iowa City, 1882; of Kansas City, Mo.; died in a hospital in Colorado Springs, Colo., August 7.

Daniel H. Artherholt (license, Ohio, years of practice, 1896), for 49 years a practitioner of Ohio; died at his home in Youngstown, August 27, from heart disease, aged 75.

James Porter Williams, M.D. University College of Medicine, Richmond, 1897; of Richmond; died in the Catawba Sanatorium, August 20, from tuberculosis, aged 40.

Philip S. Fisher, M.D. University of Pennsylvania, Philadelphia, 1868; coroner of Center County; died at his home in Zion, Pa., August 19, from nephritis, aged 68.

Carl P. Friese, (license, Illinois, years of practice) for 48 years a practitioner of Chicago; died at his home, August 28, from cerebral hemorrhage, aged 80.

Orlando Ilstrup, M.D. University of Minnesota, Minneapolis, 1899; died suddenly at his home in Cokato, Minn.; August 12, from heart disease, aged 41.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

CALOX

A Tooth Powder that Qualifies as a Nostrum

"Calox, the Oxygen Tooth Powder," is advertised as possessing "germicidal powers" which make it "the only dentifrice that will actually sterilize the oral cavity."

McKesson and Robbins, the makers, at one time made the claim that Calox gave up free oxygen from the calcium dioxid which the powder contained. In detail, the firm's claims were:

> "The basis of the preparation is a carefully selected variety of English Precipitated chalk, rendered slightly saponaceous and delicately flavored and to which is added in proper quantity calcium dioxid. It is this latter ingredient which confers upon CALOX its peculiar cleansing and germicidal properties. Calcium dioxid, like hydrogen dioxid, has the property of giving up oxygen in the nascent state when brought into contact with water or dead organic matter, at the same time forming milk of lime; it is therefore a powerful oxidizing agent, germicidal and antacid."

These claims were *misleading*, if not actually false. Calcium dioxid is practically insoluble in water and it is only that fraction which dissolves in water that gives up available oxygen. As, even according to the manufacturer's own claims, there was only 2 per cent. calcium dioxid in Calox and as only a minute fraction of that 2 per cent. is soluble, the oxidizing and germicidal powers of Calox must have been practically *nil*.

The claim has further been made that "Calox represents in powder form the therapeutic efficiency of a 2 per cent. hydrogen dioxid solution." A specimen of Calox was purchased in the open market and examined by the Association's chemists. It was found that the powder consisted largely of chalk, a small amount of soap and sugar with some oxygen-yielding substance and the whole flavored with wintergreen. Quantitative determination of the available oxygen showed that Calox contained an amount of oxygen equivalent to 0.8 per cent. hydrogen dioxid instead of the 2 per cent. claimed. In other words, the claim made for Calox was 60 per cent. false. More recently the company admits that its product contains the equivalent of only 1.5 per cent. hydrogen dioxid.

The entire available oxygen-content of Calox was found to be in its water-soluble part. As calcium dioxid is practically insoluble in water, it is evident that the oxygen in Calox is not derived from that drug as has been claimed. As a matter of fact, further examination showed that the essential oxygen-producing constituent of Calox is not calcium dioxid at all but from its properties appeared to be sodium perborate.

In this connection, some quotations from two patent specifications of dentifrices will be of interest. The first is from a patent issued May 17, 1904, to Edward C. Kirk who assigned one-half of the patent to one E. H. Gane and one other person:

> "The invention therefore consists in combining with any of the usual well-known or suitable tooth-powder materials. . . . *one of the dioxids* of the alkaline earth metals. . . ."
>
> "I have ascertained that about 2 per cent. of *calcium dioxid* is sufficient to accomplish the detergent and germicidal ends above described." [Italics ours.—Ed.]

Compare the foregoing with the following taken from a patent specification issued Oct. 17, 1905, to E. H. Gane, who assigned the patent to the exploiters of Calox, McKesson and Robbins:

> "The invention therefore consists in combining with any *of the* usual well-known or suitable tooth-powder materials. . . . *one of the* percarbonates or *perborates* of the alkali or alkaline earth metals. . . ."
>
> "I have ascertained that about 1 per cent. of percarbonate or *perborate* of the alkali or alkaline earth metals is sufficient to accomplish the detergent and germicidal ends above described." [Italics ours.—Ed.]

From the foregoing and from the further fact that the name "Calox" suggests "calcium dioxid," it is evident that Calox belongs in that class of nostrums the composition of which is changed from time to time while the name remains the same.

The later "literature" on Calox dodges the direct statement previously made that the preparation contains calcium dioxid. After stating that Calox contains chalk and castile soap with flavoring, we now read: "and to it is added the oxygen compounds, which form hydrogen dioxid when mixed with water." Nor is this all. The later advertising contains this statement:

> "Some manufacturers are offering to the *profession* 'peroxid powders' or 'peroxid pastes,' which contain metallic peroxids, but which do not contain *available oxygen*, that is, the peroxids are stable and not dissociated when mixed with water."

In other words, McKesson and Robbins charge "some manufacturers" with doing, to-day, just what McKesson and Robbins themselves did at one time.

The patents held by McKesson and Robbins give this firm the exclusive right of manufacturing tooth powders containing peroxids, perborates or percarbonates. It is another illustration of the unfair monopolies that may be secured under our present patent laws.

NATURAL AND SYNTHETIC SALICYLATES

Report of the Council on Pharmacy and Chemistry

With the view of determining the claimed superiority of "natural" salicylic acid and salicylates over the "synthetic" varieties, a practical study of the question was made under the auspices of the Committee on Therapeutic Research of the Council on Pharmacy and Chemistry. The investigations having been completed, the Council adopted the following report and authorized its publication.

W. A. PUCKNER, Secretary.

It has often been stated in medical papers, and particularly in the advertisements of manufacturers, that salicylates prepared synthetically are less effective than those prepared from the oils of wintergreen or birch, the so-called "natural" products, and that synthetic sodium salicylate is much more dangerous. These contentions, if true, should abolish the use of the synthetic products. If, on the other hand, these contentions are unfounded, there exists no good reason for the use of the much more expensive "natural" products.

To settle this question, the Committee on Therapeutic Research of the Council caused a series of investigations to be made. These showed conclusively that:

1. Contrary to certain statements in the older literature, there is no difference in the toxic dose for animals between "natural" sodium salicylate, the most highly purified synthetic, and the cheapest commercial sodium salicylate now found on the market.[1]

2. The evidence for the claimed clinical differences, as found in medical literature, is extremely unsatisfactory and inconclusive.[2]

3. No significant chemical impurities are present in commercial synthetic salicylate.[3]

4. No difference can be detected clinically, either in the therapeutic or toxic effects, if the comparison is made under conditions which strictly exclude personal bias.[4]

The Council therefore concludes that there is no difference in the actions of "natural" and synthetic salicylates, and that statements that differences exist are unfounded.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and *queries on* postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ANOTHER CONSUMPTION VACCINE

To the Editor:—I have before me the *Bacterial Therapist*, G. H. Sherman, M.D., Editor, Detroit. He has an editorial on the "Non-Virulent Tubercle Bacillus Vaccine," and reports some wonderful (?) results from it. Please inform me if there is anything to this vaccine, or is this the result of our imported friend Friedmann? C. N. CHIPMAN, M.D., Washington, D. C.

ANSWER.—This "Non-Virulent Tubercle Bacillus Vaccine" has the appearance of being simply another nostrum of the vaccine and serum variety. We have nothing but the word of the promoters regarding not only what it is, but also what it is good for. This fact alone should be sufficient to warrant throwing into the waste-basket "literature" of the kind referred to by our correspondent and published in the house organ of the firm. The reader is led to believe without specifically being told so that this vaccine is the same as, or a modification of, the notorious Friedmann preparation. Thus we are told, "It is claimed that a culture of this tubercle bacillus was originally obtained from a turtle that had tuberculosis . . . " Friedmann's "discovery" being thus hinted at, the Friedmannian source of this active-harmless preparation is stated—still somewhat guardedly—to be " . . . a culture of which bacilli was obtained last March at a hospital in New York City, where the living organism was first administered in this country . . ." How this organism was obtained we are not informed. We do not know whether it came from the original culture or from a patient. If from the latter, nothing is said as to whether it was a direct descendant of the turtle bacillus or one of the patient's organisms, modified by the treatment or otherwise. According to the promoters, the organism proposed as a remedy has been rendered non-virulent by killing it and converting it into a vaccine. So far as we can learn, therefore, the "Non-Virulent Tubercle Bacillus Vaccine" is an attenuation of Friedmann's tubercle bacillus. The experimental and other data offered have the appearance of the "made to order" kind. As we have already stated, the tone of the advertising "literature" discredits it at the outset and its doubtful parentage cannot beget much confidence in its future. There is no reason to expect more of this preparation—agreeing that it is what its promoters think it is—than of the tuberculins already well known. It is to be hoped that physicians will bear in mind recent fiascos in the line of prematurely announced consumption cures and give this Friedmann shadow a wide berth. While there is reason to hope that, if worthless, it may also prove harmless, the present insufficient data are no reason for the abandonment of the present methods.

We presume that this, like so many similar products of questionable value, will be manufactured under a "government license." It is to be hoped that the day is not far distant when Congress will give the Public Health Service authority to withhold a license for preparations of this character; such authority has been conferred on the secretary of agriculture, who can prohibit the interstate shipment of worthless serums, vaccines, etc., which are to be used in the treatment of diseases of animals. Apparently, however, the Public Health Service is forced to grant a license for almost anything provided it is made in a fairly cleanly manner and is put on the market in a sterile form.

TRACHOMA REGULATIONS IN THE DIFFERENT STATES

To the Editor:—As secretary of the Insular Board of Health of Porto Rico, I am interested in knowing which states of the Union have enacted acts regulating the prevention of trachoma. We are anxious to have the data in order to establish an efficient method to prevent trachoma. Our purpose is to know the name of the states, in order to obtain the rules and regulations concerning trachoma. JOSÉ LUGO-VIRTA, San Juan, P. R.

ANSWER.—In those states which have specifically regulated "trachoma," two methods seem to have been adopted. Either the health authorities are vested with power by the state legislature to declare diseases infectious and the like and to require that such diseases be reported, or the state board drafts certain necessary regulations which are subsequently adopted by the state in a legislative enactment. In either case such rules have the force of, or are made, the law of the state.

In Massachusetts, by ruling of the State Board of Health, trachoma was made reportable May 6, 1909; while by Chapter 75, Massachusetts Revised Laws, Section 50, all the physicians of that state must report infectious diseases and the like which come to their attention to the health authorities.

Pennsylvania by Public Laws 1909, p. 855, Section 1, requires physicians to report trachoma either to a local health officer or to the State Department of Health. Osteopaths are likewise required to report these diseases. The state commissioner of health has power to issue any further necessary regulations.

The Texas Sanitary Code was enacted into law, March 3, 1911. All persons infected with trachoma are to be excluded from schools and any similar public place in which persons may congregate unless by a physician's certificate there is sufficient warrant that all dangerous inflammation has disappeared.

The Washington State Board of Health is vested with power to declare a disease infectious and the like. Trachoma is reportable and physicians must, in writing within twenty-four hours, notify the nearest health officer of all such infections.

By Act 125, Laws of Hawaii, 1911, Section 3, trachoma was declared to be infectious, and by Revised Laws, Section 1004, all physicians are required to report the disease to a proper health authority.

A large number of the states have not legislated specifically on this subject. But such jurisdictions have apparently contented themselves with vesting their health authorities with power to take all needful precautions in regard to any dangerous diseases and the like. In a few states, under laws providing for the physical inspection of schoolchildren, parents and guardians are required to furnish proper care in a case in which a child's eyes may become infected or the like, as in Connecticut, Chapter 104, Act 1899, and Chapter 40, Act 1901. In the Sanitary Code of 1911, Louisiana furnishes a good example of vesting the State Board of Health with the necessary power to declare a given disease infectious and the like.

BINET TEST—SUBCUTANEOUS ADMINISTRATION—"INFANTILE PARALYSIS"—RUSSIAN OIL

To the Editor:—Please answer the following:

1. Where can I find the Binet tests for defective children, as modified by Dr. Goddard?

2. What, if any, are the advantages of the subcutaneous method of administering iron, arsenic and strychnin by ampules over other methods of administering these remedies?

3. Is it correct to speak of an adult as suffering from a recent case of "infantile paralysis"?

4. Is there an oil with "Russian-sounding name" now prescribed by best New York physicians "for chronic constipation"? This is the indefinite statement of a recent patient, who seems surprised that I cannot at once state the name of the remedy.

J. E. Heath, Gardiner, Me.

Answer.—1. This method is described in "Modern Treatment of Nervous and Mental Diseases," by White and Jelliffe, Vol. I, p. 158 (Philadelphia, Lea and Febiger, 1913).

2. The subcutaneous method avoids irritation of the stomach or intestines. It may secure more certain absorption. Usually, however, the ordinary method of administration secures the desired results.

3. The disease commonly called "infantile paralysis" has been designated as "acute anterior poliomyelitis." Recent investigations show that the lesions are more extensive than formerly supposed and not confined to the anterior gray matter of the cord. Hence the term "anterior poliomyelitis" becomes inappropriate as it does not cover all cases of the disease. While it seems somewhat absurd, it may, however, be excusable to speak of an adult as suffering from an attack of "infantile paralysis."

4. The oil referred to is probably a proprietary preparation of a paraffin oil. So far as we know, paraffin oil is coming into use in cases of chronic constipation, but we are not sure that Russian oil is now prescribed by the best New York physicians. Liquid petrolatum will serve the same purpose in treating constipation.

SUITABLE METHODS OF ADMINISTERING DRUGS—PALATABLE SOLUTIONS OF VERONAL

To the Editor:—Will you favor me with formulas for making palatable solutions of veronal? C. O. M., Boston.

Answer.—The most palatable solutions of veronal are those obtained by dissolving the dose to be administered in a glass of warm milk or in water, as warm as can be drunk, flavored with a little lemon juice. If the patient objects to taking hot drinks, veronal, which requires 150 parts of cold water for solution, may be replaced by the sodium salt of veronal (sodium diethyl-barbiturate) which is soluble in five parts of water at ordinary temperature. This soluble salt of veronal is marketed as veronal-sodium and medinal (see N. N. R., 1913, p. 78). As veronal-sodium has a bitter, alkaline taste it is best given largely diluted with water. Elixirs of veronal and of veronal-sodium may be prepared, but in general the sweet taste accentuates the taste of veronal. These elixirs are also objectionable because of their alcohol content.

To the Editor:—Have you any publications useful for the doctor who dispenses, which will aid him in preparing and dispensing palatable mixtures? Kindly inform me of any such publications and the price. F. J. Dodd, M.D., Pembroke, Ontario.

Answer.—The following publications contain much information of value to physicians both as to the writing of prescriptions and their compounding:

Beal, J. H.: Prescription Practice and General Dispensing, An Elementary Treatise for Students of Pharmacy, published by the author, Scio, Ohio, 1907.

Fantus, Bernard: A Text-Book on Prescription-Writing and Pharmacy with Practice in Prescription-Writing, Laboratory Exercises in Pharmacy and a Reference List of the Official Drugs, Especially Designed for Medical Students, Chicago Medical Book Company, 1906.

Physicians should have little difficulty in preparing drugs for administration if they will take the trouble to learn the properties—taste, solubility, chemical incompatibilities, etc.—of the remedies which they use and if they will avoid complex mixtures. Thus an understanding of the physical properties of veronal (see preceding inquiry) will readily suggest suitable methods of administration.

TREATMENT OF CONSUMPTION BY WORK AND EXERCISE

To the Editor:—What articles covering work and exercise in the treatment of consumption have appeared recently? M. D. S.

Answer.—The following articles have reference to treatment of consumption by work and exercise:

Flinn, J. W.: Rest and Repair in Pulmonary Tuberculosis, The Journal, Aug. 16, 1913, p. 466.

Teleky, L.: Choice of Occupation with Regard to Tuberculosis, *Wien. klin. Wchnschr.*, March 13, 1913; abstr., The Journal, April 26, 1913, p. 1336.

Halcomb, S. R. C.: Graduated Labor in Pulmonary Tuberculosis, *Military Surgeon*, February, 1913; abstr., The Journal, Oct. 26, 1912, p. 1564.

Allan, J. W.: Graduated Labor at Bellefield Sanatorium, *Glasgow Med. Jour.*, January, 1911; abstr., The Journal, Feb. 4, 1911, p. 384.

Francini, A. P.: Rest, Exercise and Food in the Management of Tuberculosis, *New York Med. Jour.*, Dec. 31, 1910; abstr., The Journal, Oct. 29, 1910.

Paterson, M.: Treatment of Pulmonary Tuberculosis by Graduated Rest and Exercise, *Practitioner*, January, 1913.

MacCorison, C. C., and Burns, N. B.: Method of Recording Exercise Data in Sanatorium for Consumptives, *Boston Med. and Surg. Jour.*, May 9, 1912.

EFFECT OF EUCAIN

To the Editor:—It is stated by P. LeMee (*Ann. d. mal. de l'oreille, du larynx, etc.*, Nov. 9, 1912) that beta-eucain is a vasodilator. The "American Text-Book of Surgery," 1899, p. 1103, states that "from a clinical point of view, eucain produces just as rapid, profound and lasting anesthesia as cocain, but is less dangerous. Occasionally, however, local gangrene as a result of vasomotor constriction has been observed."

Please advise me which is correct.

P. O. Chaudron, M.D., Dothan, Ala.

Answer.—Pharmacologists agree in stating that eucain does not constrict the blood-vessels. Hyperemia is produced rather than anemia.

EFFECT OF ALTITUDE ON BLOOD-PRESSURE

To the Editor:—In the Queries and Minor Notes column of The Journal (Sept. 6, 1913, p. 787) you refer to blood-pressure and the effect of altitude. For six years past we have been studying the effect of altitude on blood-pressure in consumptives at an elevation of 6,000 feet. Our first report was published in the *Archives of Internal Medicine*, August, 1908. This report covered but one hundred cases, but our findings in six hundred cases were reported before the American Medical Association at Minneapolis this year. This article will be published in the *Archives of Internal Medicine* in the near future. We think we have shown conclusively that altitude tends to raise blood-pressure rather than lower it, both in consumptives and in normal persons living at high altitudes. The fact that our studies cover six hundred cases seems to us to offset any former observations, such as Gardner and Hoaglund's, which took into consideration so few patients that the facts can be of little scientific value compared to a larger study.

We at least feel that in referring to blood-pressure work and altitude our findings deserve as much consideration as the references to which you refer.

L. S. Peters, M.D., Silver City, N. Mex.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF POST-GRADUATE WORK, CONTRACT PRACTICE, LEGISLATION, MEDICAL DEFENSE, AND OTHER MEDICOLEGAL AND ECONOMIC QUESTIONS OF INTEREST TO PHYSICIANS

The Present Legal Status of Osteopathy

Frequent inquiries are received regarding the present laws regulating osteopathy in different states. The study of the efforts made at regulation of this cult by the different state legislatures is most interesting. Early in its development its adherents began agitation for separate boards of examination and license. In nineteen states such laws have been enacted. In others, some kind of compromise or half-measure has been adopted.

Those states now having separate osteopathic boards of examiners, with the date of passage of the present law are:

Arkansas	1903	Montana	1905
Connecticut	1901	Nebraska	1909
Florida	1909	New Mexico	1905
Georgia	1909	New Hampshire	1911
Idaho	1907	North Dakota	1909
Kansas	1913	Pennsylvania	1911
Louisiana	1908	South Dakota	1907
Michigan	1903	Tennessee	1905
Minnesota	1903	Vermont	1909
Missouri	1907		

In twelve states amendments to the medical practice act have been adopted, providing for the appointment of one or more osteopaths on the examining board. These states are:

Arizona	1913	Oklahoma	1907
Indiana	1905	Oregon	1907
Iowa	1902	Texas	1907
Kentucky	1904	Utah	1907
Massachusetts	1911	Washington	1909
New York	1907	Wisconsin	1903

Ten states have enacted laws permitting the state board of medical examiners to examine and license osteopaths either as such or as practitioners of medicine:

California	1913	Ohio	1906
Colorado	1910	South Carolina	1904
Delaware	1907	Virginia	1911
New Jersey	1910	West Virginia	1907
North Carolina	1909	Wyoming	1905

In Illinois, the act of 1911 permits the State Board of Health to examine and license osteopaths at their discretion, but those so licensed cannot use medicine internally or externally, or perform surgical operations. By the revised laws of Maryland for 1902, "masseurs or other manual manipulators who use no other means" are exempted therefrom. This language would seem to apply to osteopaths.

To-day there are but five states in which no legislative steps have been taken to regulate the osteopaths as such:

Alabama
Maine
Mississippi
Nevada
Rhode Island

Is Osteopathy the Practice of Medicine?

In fifteen states either by judicial interpretation or by statutory enactment, osteopathy is included within the meaning of the term "practice of medicine." These states are: Alabama, California, District of Columbia, Illinois, Iowa, Nebraska, New York, New Hampshire, Nevada, Ohio, Texas, Utah, Virginia, West Virginia, Wyoming. In thirty-two states osteopathy is not the practice of medicine. These are: Arkansas, Arizona, Colorado, Connecticut, Delaware, Florida, Georgia, Idaho, Indiana, Kansas, Kentucky, Louisiana, Maryland, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, Montana, New Jersey, New Mexico, North Carolina, North Dakota, Oklahoma, Oregon, Pennsylvania, Rhode Island, South Carolina, South Dakota, Tennessee, Vermont, Washington, Wisconsin. In one state, Maine, it seems that the question has never arisen for judicial interpretation, so that the present status of osteopathy there remains uncertain.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ARIZONA: Phoenix, October 7-8. Sec., Dr. John Wix Thomas, Phoenix.

COLORADO: State Capitol, Denver, October 7. Sec., Dr. David A. Strickler, 612 Empire Building.

GEORGIA: Regular, State Capitol, [illegible] Sec. Dr. C. T. Nolan, Marietta; Homeopath [illegible] 1. Sec., Dr. R. E. Hinman, 106½ Whitehall St.; Eclectic, State Capitol, Atlanta, October 14. Sec., Dr. C. W. Miller, 192 W. North Ave.

IDAHO: Boise, October 7. Sec., Dr. John F. Schmershall, Jerome.

ILLINOIS: Coliseum Annex, Chicago, September 24-26. Acting Sec., Amos Sawyer, Springfield.

KANSAS: National Hotel, Topeka, October 14. Sec., Dr. H. A. Dykes, Lebanon.

LOUISIANA: New Orleans, October 27-29. Sec., Dr. A. B. Brown, 34 Cusachs Building.

MICHIGAN: Capitol Bldg., Lansing, October 14-16. Sec., Dr. B. D. Harison, 504 Washington Arcade, Detroit.

MINNESOTA: University of Minnesota, Minneapolis, October 7-10. Sec., Dr. Thomas S. McDavitt, 814 Lowry Building, St. Paul.

MISSISSIPPI: Jackson, October 28-29. Sec., Dr. E. H. Galloway, Jackson.

MONTANA: State Capitol, Helena, October 7. Sec., Dr. Wm. C. Riddell, Helena.

NEW JERSEY: State House, Trenton, October 21-22. Sec., Dr. H. G. Norton, 429 E. State Street.

NEW MEXICO: Santa Fe, October 13. Sec., Dr. W. E. Kaser, East Las Vegas.

NEW YORK: September 23-26. Chief of Examinations Division, Mr. Harlan H. Horner, Department of Education, Albany.

OKLAHOMA: Muskogee, October 14. Sec., Dr. John W. Duke, Guthrie.

RHODE ISLAND: State House, Providence, October 2-3. Sec., Dr. Gardner T. Swarts.

UTAH: Salt Lake City, October 6-7. Sec., Dr. G. F. Harding, 310 Templeton Building.

WYOMING: State House, Cheyenne, October 15. Sec., Dr. J. B. Tyrrell, Laramie.

Additional Data for, and Corrections of, the Educational Number

The following additions and corrections should be made to the data published in the latest educational number of THE JOURNAL, that of Aug. 23, 1913:

In Table 1, on page 591, the fees charged by the University of Oklahoma School of Medicine for the four years, respectively, should have been $50, $29, $10 and $15. A letter from an officer of the school named states that these are laboratory fees and deposits, no tuition fees being charged.

Also in Table 1, on page 591, in line 45, for the University of Maryland School of Medicine, instead of three graduates having degrees from the college of liberal arts, there were five graduates having such degrees.

On page 582, in accordance with an official statement from the Missouri State Board of Health, the Hippocratean College of Medicine was marked by an asterisk (*), indicating that the school, during its existence, was "not in good standing with the home state licensing board." A letter just received from the secretary of the Missouri State Board informs us that at the time the school merged with the Barnes Medical College of St. Louis, now the American Medical College, a ruling was adopted by which two years' credit might be allowed for the completion of three years' work at the Hippocratean College of Medicine, or one year's credit might be allowed for two courses completed in that school, but that no credit could be given for the completion of one year's work.

In Table 2, on page 594, the second line 91 should have been line 92, Jefferson Medical College, Philadelphia; the figures in the balance of the line are correct.

On page 587, second column, Temple University, Department of Medicine, was included among medical colleges which were to require a year of college work, including physics, chemistry and biology, for the session of 1913-1914. Later information shows that the requirement will not begin until in 1914.

In the last line on page 587, also, the higher requirement for the state licensing board of California affects all candidates in 1919 and thereafter, or students matriculating for and after the session of 1915-1916.

Michigan May Report

Dr. B. D. Harison, secretary of the Michigan State Board of Registration of Medicine, reports the written examination held at Detroit, May 22-24, 1913. The number of subjects examined in was 14; total number of questions asked, 100; percentage required to pass, 75: The total number of candidates examined was 34. all of whom passed. The following leges were represented:

The following questions were asked:

ANATOMY

1. Locate and describe the scapula. 2. Give the course and relations of the brachial artery. 3. Give the boundaries of the fourth ventricle. 4. What structures pass through the jugular foramen? 5. Describe the urinary bladder of a male and give its relations.

PHYSIOLOGY

1. Name the principal varieties of connective tissue. Where are they found and what purpose do they serve? 2. State the disposition of the fat principles of food after digestion; carbohydrate principles; effect of alcohol in small quantities with food. 3. What is undestood by absorption? 4. Name four forces concerned in the circulation of the blood. 5. What effects do extremes of temperature have on respiration? What effect has age? 6. Describe the suprarenal capsules. What is their function? 7. What is the influence of the nervous system in the production of sweat? 8. Name the five laws of reflex action (Pflüger). How do they work? 9. Describe the process known as ovulation. 10. Describe the function of the tympanic membrane; eustachian tube.

PATHOLOGY

1. By what agencies does the body protect itself against the entrance and harmful effects of pathogenic bacteria? 2. Describe morbid anatomy of bronchopneumonia. 3. What changes take place in extravasated blood? Name them. 4. What changes take place in an inflamed part, causing redness and swelling? 5. Describe the process of primary healing; of secondary healing.

CHEMISTRY

1. Give properties and chemical formulas of (*a*) carbon dioxid; (*b*) carbon monoxid. 2. Give a test for indican and state its clinical significance when found in urine. 3. Define (*a*) aldehyd; (*b*) alkaloid (*c*) glucosid. 4. Name and differentiate the three classes of sugar. 5. What are proteids and from what are they derived?

PRACTICE

1. Name the different forms of non-malignant stricture of the rectum. How far above the anus is a simple stricture usually found? 2. Describe your procedure in making a physical examination of the abdomen. 3. Describe the urinary findings in diabetes mellitus and chronic interstitial nephritis. 4. Make a differential diagnosis of pleuritic and pericardial effusion. 5. Define and give etiology of neuritis. 6. Give pathology of typhoid fever. Name 7. Give symptoms and management of between renal and hepatic colic. 9. Give the differen of variola. 10. Give the differential diagnosis between paralysis agitans and tabes dorsalis.

SURGERY

1. Discuss acute osteomyelitis. 2. Describe complete inguinal hernia; give symptoms of strangulation and treatment. 3. Name varieties of goiter and mention the indications for surgical interference. 4. What lesions would you consider in a severe injury about the ankle-joint. 5. In an oblique fracture of the lower third of the femur, state the usual position and give the muscular control of the fragments.

DIAGNOSIS

1. State the difference between organic and functional murmurs. 2. Describe method of examining the size of the spleen. 3. What is the diagnostic significance of edema of one arm and hand? 4. Describe rales, mention varieties and state diagnostic significance. 5. What are friction sounds and what do they signify? 6. What pathologic significance has an increased vocal fremitus? 7. What is dyspnea and what does it signify? 8. Describe diagnostic indications from the character of cough. 9. Describe aphasia: name varieties in reference to localized lesions. 10. In what pathologic conditions is ocular paralysis present?

OBSTETRICS

1. State your views with reference to examinations and what you would expect to learn by them. 2. Name some of the causes and give treatment of hemorrhage after labor. 3. How would you distinguish one shoulder from the other, when the hand and arm cannot be reached? 4. Outline general scheme of treatment for persistent and pernicious vomiting of pregnancy. 5. Give diagnosis and management of the third position of the vertex.

DERMATOLOGY, SYPHILOLOGY AND DISEASES OF THE EYE, EAR, NOSE AND THROAT

1. Describe infantile eczema; outline its treatment. 2. Differentiate scabies from prurigo. 3. How do you recognize and treat scabies? 4. Describe the initial lesion of syphilis. 5. Briefly outline treatment of syphilis. 6. What faulty anatomic condition of the eye constitutes myopia, and how can it be corrected by lenses? 7. Describe simple chronic rhinitis. 8. Describe otitis media purulenta and mention possible complications. 9. Describe iritis; give causes and treatment. 10. Describe laryngeal tuberculosis.

MATERIA MEDICA AND THERAPEUTICS (REGULAR)

1. Briefly discuss the serum and vaccine theories. 2. Name four principal serums, give mode of administration, dose and use of each. 3. What drugs would you use in anemic conditions? Write two prescriptions using the drugs named. 4. Mention two intestinal antiseptics. Give therapeutic use and dose of each. 5. Name three hypnotics: indicate use and dose of each. 6. State the physiologic action, use and administration of hot and cold water. 7. Name two cardiac stimulants and sedatives and indicate dose of each. 8. Give the composition of Dover's powder. State its action, use and dose. 9. Give the physiologic action of nux vomica, name its principal alkaloid and state its use and dose. 10. Give the range of indications for the use of galvanism and high-frequency currents.

MATERIA MEDICA AND THERAPEUTICS (HOMEOPATHIC)

1. Briefly discuss the serum and vaccine theories. 2. State physiologic action, use and administration of hot and cold water. 3. Differentiate between bryonia, phosphorus and causticum in pulmonary affections. 4. Differentiate between nux vomica, carbo veg. and pulsatilla in gastro-intestinal diseases. 5. Name three principal alkaloids of opium, give physiologic dose and antidote treatment for poisoning by one. 6. Give leading characteristics for calcarea carbonicum: sabina; mercurius dulcis. 7. Name three hypnotics; give use and dose of each. 8. Give range of indications for the use of galvanism and high frequency currents. 9. Name four principal serums, give mode of administration, dose and use of each. 10. Name two snake poisons and give general indications for their use.

MATERIA MEDICA AND THERAPEUTICS (ECLECTIC)

I Name some agents used for active hemorrhage. For passive hemorrhage. Give methods of use. 2. In what class of diseases would you prescribe iris versicolor? 3. What symptoms or specific indications call for hacrotys? 4. What is santonin? For what used? Give dose. 5. Give specific indications for apocynum. 6. Give properties, uses and doses of pulsatilla. 7. In what class of diseases and in what form and dose would you prescribe bryonia? 8. In what conditions of the heart would you prescribe digitalis? 9. When is nux vomica to be prescribed? 10. Give range of indications for the use of galvanism and high-frequency currents.

Book Notices

THE MODERN HOSPITAL. Its Inspiration: Its Architecture: Its Equipment: Its Operation. By John Allan Hornsby, M.D., Secretary Hospital Section, American Medical Association, and Richard E. Schmidt, Architect. Cloth. Price, $7 net. Pp. 644, with 207 illustrations. Philadelphia: W. B. Saunders Company, 1913.

Though the authors of this book acknowledge its unfinished character and have anticipated many criticisms which might be made, yet it is a most comprehensive book and covers the large subject of the modern hospital in a most satisfactory manner. The book has reference particularly to the great hospital located in the large city, though the hospital adapted for the smaller city and town has not been neglected; indeed, most or many of the principles applied to the founding, equipment and management of large hospitals are applicable to smaller institutions. It has been the aim of the authors, an architect and a practical hospital manager of many years of experience in one of our large institutions, educated as a physician, to cover the subject from almost every conceivable aspect. The architect for his part has described plans, material and other details of construction and much of the permanent interior equipment of the building. The physician has supplemented this with his ideas of plan and structure and equipment gathered from long experience and much thought on every detail of hospital requirements.

The major portion of the book, of course, is written by the physician, and though the book covers only a little more than 600 pages, the amount of detail in it is really astonishing. It covers the subject of the founding of the hospital and who should be its founders, its character, whether charity, mixed or private, its sources of support, and its running expenses. The latter, together with the cost of construction of the hospital, are discussed not only in a general way, but in detail, giving figures. It is said of the preliminary plans for a hospital that they should not be left to any architect alone, no matter how experienced, but should be discussed by every one interested, so as best to meet the demands for which the hospital is to be adapted. As to the running expenses, the principle is announced that they should be based on the best service and not on the cheapest. Getting down to actual figures, it is stated that the expenses in either a large or small hospital will average about $2.50 per patient per day. The duties of trustees, boards of directors, boards of lady managers, superintendents and heads of departments are discussed in a comprehensive way. On many of these matters, of course, only opinions or general conclusions can be stated, but an attempt is made to view all of the questions from every side, and this is characteristic of the book throughout.

In the matter of the equipment of the hospital, no detail would seem to have been overlooked from surgical operating-room to laundry, from roof-garden and sun-parlor to the vegetable cellar. Here again the experience and preferences of the authors figure largely, and in a multitude of details wide differences would be found in the opinions of different people. Likewise, in the sections on hospital management, the personnel, the hospital staff, hospital interns, head nurses, nurses, etc. These sections are among the most valuable in the book. They are written in a most spirited and interesting manner. Definite opinions are expressed on hospital management, and strong emphasis on all occasions is laid on the necessity for wide authority in the superintendent, who is the general manager of the institution, subject always to the oversight and revision of the board of directors.

Not the least valuable portion of the book is the section on business management, which sets forth complete details of the routine of the business office, referring to the entrance and discharge of patients, the keeping of records and books of account, purchase of supplies, etc.

The subject is such a large one that it is impossible to take up, either to commend or to criticize, many of the details. The book might be criticized, however, on the score of arrangement. It would seem that many of the purely architectural or equipment features of the building, which are discussed in various places throughout the book, might have been brought together more closely under the one head of structural features. In other respects also the subjects might be brought together instead of being discussed in several different places. These details of arrangement, however, can be corrected in a future edition of the book. Mechanically, it is well executed and is well illustrated.

The authors anticipate a criticism as to the illustration and recommendation of certain apparatus manufactured by certain firms or individuals. In view of the authors' statements in regard to this matter it cannot probably be regarded as objectionable. The book covers so many aspects of a modern hospital that it is in a class by itself. No other work with which we are acquainted has attempted to cover it so completely. A reading of this book could not help but be extremely valuable to municipalities, associations or persons contemplating founding a hospital, and it will prove profitable reading to every one interested in hospital management even though they differ widely with the authors in many of the details.

How to Collect a Doctor Bill. By Frank P. Davis, M.D. Cloth. Price, $1. Pp. 98. Newark, N. J.: Physicians' Drug News Company, 1913.

This is largely devoted to an abstract of the exemption laws in the different states. A table giving the time limits for accounts in the different states is convenient for reference. One's opinion regarding some of the practical advice will depend considerably on his attitude toward his profession. The advice to physicians to secure an order from a corporation, signed by a responsible person, before rendering service for which the corporation is expected to pay, is thoroughly sound. Many of the suggestions regarding bookkeeping and business methods can be read with profit by many physicians. Few physicians, however, would care to develop dunning letters to the point of referring, in Letter 3, to "the little child of the delinquent debtor, up in heaven looking down with her angelic eyes, wondering why you did not pay the doctor who worked so hard to give her ease." This would hardly do for a stereotyped letter, so it is provided that "if your patients do not die you might speak of the innocent babe who will grow up to womanhood unpaid for." Of course, you might if you cared to, but some physicians would not care to.

A Course in Normal Histology. A Guide for Practical Instruction in Histology and Microscopic Anatomy. By Rudolph Krause, A.O., Professor of Anatomy at the University of Berlin. Translation from the German by Philipp J. R. Schmahl, M.D. Cloth. Two Parts. Part I. Price $0.75 net. Pp. 86, with 30 illustrations. Part II. Price, $5.50. Pp. 406, with 208 illustrations. New York: Rebman Company, 1913.

This work is published in two separate parts, or volumes. Part I is devoted to the laboratory phase of histology—a description of the microscope, its use and care and general microtechnic. Part II is devoted to the didactic part of histology. This part is divided into lessons, making it particularly suitable as a laboratory guide. The most commendable feature of the work, aside from the arrangement of the subject, are the many beautiful illustrations in black and white and in colors. There can be little original work in a text-book on histology. It is good or bad, depending on the number and value of the illustrations. This work leaves nothing to be wished for. The illustrations are splendid and the student of histology can do no better than to study the illustrations in this book if he would have a good working knowledge of histology. The text supplements the illustrations splendidly.

The Surgery of the Stomach. A Handbook of Diagnosis and Treatment. By Herbert J. Paterson, M.A., M.C., M.B. Cloth. Price, $3.50 net. Pp. 312, with 74 illustrations. New York: William Wood & Company, 1913.

The author has written much of value on this subject which, with much more, is gathered together here. Although a surgeon he lays great stress on the value of a chemical analysis of the gastric contents; in fact, he would have the stomach-tube be a part of the armamentarium of every practitioner so that he can carry out the ordinary qualitative tests and estimate the total acidity. He says that the practitioner, be he consultant or otherwise, who, without the aid which such investigation affords, continues to treat the patient suffering from persistent indigestion or gastric pain, is acting unfairly to his patient and unjustly to himself. He believes that the greater use of the stomach-tube would reduce the mortality from stomach cancer, which, he says, can be treated successfully if diagnosed early. The operation of gastrojejunostomy he terms the keystone of gastric surgery, although not a panacea for all the ills to which the stomach is heir. The methods of investigation of gastric cases, the operations on the stomach, and the preparation of the patient for operation and treatment after operation are all described clearly and concisely. About half the book is devoted to the discussion of gastric and duodenal ulcers. The illustrations, though few in number, are well made. The author has presented in an admirable manner much that is of value to the general practitioner as well as to the surgeon. The book is a commendable one.

Prevention and Control of Disease. By Francis Ramaley, Ph.D., Professor of Biology in the University of Colorado, and Clay E. Giffin, B.A., M.D., Instructor in Surgery in the University of Colorado. Cloth. Price, $3. Pp. 386, with illustrations. Boulder, Colo.: The University Store, 1913.

This book is an attempt to describe for the general public the modern conceptions and knowledge of infectious diseases, and their control and prevention. This is done in order to bring before the intelligent citizen facts necessary to make him sympathetic toward the efforts of health officers and charitable organizations in their campaigns for the stamping out and control of disease. Among the subjects described in non-technical language are various infectious types of disease and the bacteriology, when it is known; the germ theory of disease and the life history of micro-organisms; plant and animal parasites; disinfection and disinfectants; the questions of susceptibility, resistance and immunity; the problem of vaccination; wound infections; some of the protozoal diseases, and the reasons for the rules of hygiene and sanitation. We like the idea of the book. There is tremendous general interest in all that pertains to health conditions, and much is published in the lay press, a part of which at least is not presented in a desirable or accurate form. It is essential that the public should have correct information on these subjects and this book is intended to impart this. Progress in the bacteriology of the infections is so rapid that although this book has just come from the press, we can see where revision must soon be made, even if some of the statements should not already be modified.

Foods: Their Origin, Composition and Manufacture. By William Tibbles, L.L.D., M.D., L.R.C.P., Medical Officer of Health, Nottingham. Cloth. Price $5 net. Pp. 950. Chicago: Chicago Medical Book Company, 1912.

The composition and purity of foods is everywhere receiving wide-spread attention. The importance of dietetics in the etiology and treatment of disease has long been recognized by the medical profession, but it is only within the last few years that the relation of the subject to the health of nations has been seriously considered. The literature of the chemistry of foods is voluminous and is widely scattered; consequently a work of this kind, which contains a great amount of information concerning the origin, composition and manufacture of foods collected from the literature, will prove of value to all who are interested in dietetics. The work is concerned chiefly with the composition of foods and not with their therapeutic uses. Consequently its value to the general practitioner will lie for the most part in its use as a reference work.

Ophthalmoscopic Diagnosis. Based on Typical Pictures of the Fundus of the Eye with Special Reference to the Needs of General Practitioners and Students. By Dr. C. Adam, Assistant at the Kgl. Univ.-Augenklinik, Berlin. Translated by Matthias Lanckton Foster, M.D., Ophthalmic Surgeon to the New Rochelle Hospital. Cloth. Price, $6 net. Pp. 229, with 152 illustrations. New York: Rebman Company, 1913.

This valuable work on the fundus pictures has been dedicated to the late Julius von Michel of Berlin. Especial stress is laid on local fundus findings suggestive of the presence of general disease. The consideration of the subject of myopia is unusually thorough and original. Excellent plates in color illustrate the text.

THE CATARRHAL AND SUPPURATIVE DISEASES OF THE ACCESSORY SINUSES OF THE NOSE. By Ross Hall Skillern, M.D., Professor of Laryngology, Medico-Chirurgical College. Cloth. Price, $5. Pp. 389, with 253 illustrations. Philadelphia: J. B. *Lippincott* Company, 1913.

To set forth in English a thorough and exclusive treatment of the accessory sinuses of the nose has been the author's aim. He seems to have succeeded remarkably well. The book is divided into two parts. In Part I are discussed the anatomy and development of these sinuses, their physiology and bacteriology, the general etiology of sinus disease, the normal mechanism of drainage, cause of chronicity, pathology, symptoms, diagnosis and treatment. In Part II the individual sinuses receive consideration, the frontal, maxillary, ethmoid and sphenoid. The author has endeavored to supply in about 400 pages all that is known of these sinuses, illustrated by many splendid drawings and skiagrams. There are over 250 illustrations, none of which appears to be useless or without value. The book cannot fail to be received with favor. There is also a good and extensive bibliography and the references are placed at the bottom of the page on which they are mentioned, so that there is no need for unnecessary turning of pages in a wild search for a particular reference. Consecutive numbering obviates error and confusion.

FREUD'S THEORIES OF THE NEUROSES. By Dr. Eduard Hitschmann. Authorized Translation by Dr. C. R. Payne, with an Introduction by Ernest Jones, M.D., M.R.C.P. Paper. Price, $2. Pp. 154. Nervous and Mental Disease Monograph Series No. 17. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

While Freud's theories are much talked about, but few English-speaking physicians have had the opportunity to acquaint themselves with the essentials of Freud's writings, which are scattered and rather fragmentary. Two books dealing with Freud's theories have recently appeared in English and have received favorable comment in these columns. And now appears a translation of Hitschmann's book, which is an effort at a synthetic presentation of the Freudian theory. Truly, at present there is no excuse for any one to discuss Freud without knowing something about him. Hitschmann, it must be stated, is a close friend and pupil of Freud and especially qualified to give a faithful presentation of both the theory and practice of psychanalysis. The translation is exceptionally good, bearing in mind that the majority of English translations from the German are too literal.

THE RELATIONS OF THE LACRIMAL ORGANS TO THE NOSE AND NASAL ACCESSORY SINUSES. By Prof. Dr. A. Onodi, Director of the Rhinolaryngologic Clinic in the University of Budapest. English Translation by Dr. Dan McKenzie. Cloth. Price, $4.25 net. Pp. 66, with 45 illustrations. New York: William Wood & Co., 1913.

Onodi has established his right to be regarded as authority on nasal relations, and in his latest work on the relations of the lacrimal apparatus to the nose his former high standard is maintained. The previous publications on the anatomy of this region have been far from exhaustive, and it is now especially important to have a clear idea of the anatomic relations, as many new operative procedures on the lacrimal organs are being proposed. The book contains sixty-six pages of text published in the original German, accompanied by the French and English translations, illustrated by photographic plates showing forty-five preparations. The price seems rather large since all the English material in the book could be given in a book one-third the size, with a corresponding reduction in price.

HYPNOTISM AND DISEASE. A Plea for Rational Psychotherapy. By Hugh Crichton Miller, M.A., M.D. With an Introduction by Charles Lloyd Tuckey, M.D. Cloth. Price, $1.50 net. Pp. 252. Boston: Richard G. Badger, 1912.

The author of this little volume is no fanatic on the subject of hypnotism. He appears to have a well-balanced opinion of its possibilities and also of its limitations. The book is a popular exposition of the entire subject and "is addressed to the intelligent layman as well as the open-minded doctor, who, not having studied the subject for himself, is willing to make a preliminary survey of the field." Though the author may be mistaken when he calls hypnotism *rational* psychotherapy, yet it constitutes a distinct and, in some instances, indispensable form of psychotherapy, which medical men should understand, even though it be for the purpose of condemning its universal application. The book constitutes splendid summer reading, not being weighted down with too many technical terms.

ACUTE POLIOMYELITIS (HEINE-MEDIN'S DISEASE). By Dr. Ivan Wickman. Authorized English Translation by Dr. William J. A. M. *Maloney*, F.R.S. Nervous and Mental Disease Monograph Series. No. 16. Paper. Price, $3. Pp. 135, with illustrations. New York: The Journal of Nervous and Mental Disease Publishing Company, 1913.

The well-known monograph on acute poliomyelitis by Dr. Ivan Wickman has at last been published in English. The translation by Dr. Maloney, though faithful to the German text, is not too literal to distract the reader's attention from substance to form. As indicative of the value of this splendid monograph it may be stated that scarcely a report or a review on acute poliomyelitis appears without repeated references to Wickman's work; indeed, Lewandowsky in his extensive "Handbuch der Neurologie" incorporated the entire monograph as Wickman's contribution to the subject. Of especial value to those wishing to pursue the subject further is the complete bibliography at the end of the volume.

OBSTETRIC AND GYNECOLOGIC NURSING. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia. Fourth Edition. Cloth. Price, $1.75 net. Pp. 480, with illustrations. Philadelphia: W. B. Saunders Company, 1913.

When a book of this character has gone to four editions in twelve years, little need be said regarding its worth. The book has been thoroughly revised and enlarged by Dr. Davis. It is printed in large, clear type and the illustrations are, as a rule, admirable. Some of them, however, show the effects of wear through use in various editions. While the subject matter is excellent and up-to-date and the type large and clear, the book is printed on such heavy paper that its bulk and weight are almost oppressive, and it would seem that this defect should be remedied in subsequent editions.

INSURANCE MEDICINE. Being Suggestions to Medical Examiners. By Henry H. Schroeder, M.D., Medical Director, Mutual Life Insurance Company of New York. Cloth. Price, $2 net. Pp. 150. New York: William Wood & Company, 1913.

This little book is a compilation of the "Suggestions to Medical Examiners" which have appeared from time to time in the New York *Medical Record*, and contains many practical suggestions and much good advice for the medical examiner for life insurance. It possesses the additional advantage of being brief. Chapters 6 and 7, on "Completion of the Examiner's Report" and "Fraudulent Practices," are especially interesting and of value to the medical examiner for life insurance.

FORTSCHRITTE DER NATURWISSENSCHAFTLICHEN FORSCHUNG. Herausgegeben von Prof. Dr. Emil Abderhalden, Direktor des Physiologischen Institutes der Universität Halle a. S. Volume VIII. Paper. Price, 15 marks. Pp. 308, with 218 illustrations. Berlin: Urban & Schwarzenberg, 1913.

In this volume the medical reader will find two articles of immense interest. "Our Knowledge of the Oldest Tetrapodes," by F. Broili of Munich, is a profound historical study of the entire subject, profusely illustrated and easily understood. The second article, no less interesting, is the one written by Dr. C. Wesenburg-Lund, Hillerod (Denmark), on "Propagation of Sweet-Water Insects, Their Mating and Egg-Deposition."

DISEASES OF THE EYE. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. deSchweinitz, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania. Seventh Edition. Cloth. *Price, $5 net.* Pp. 979, with 367 illustrations. Philadelphia: W. B. Saunders Company, 1913.

This edition contains many of the new ideas which time has shown to be important. Among the additions are special paragraphs on trephining in glaucoma, Toti's operation on the lacrimal apparatus, rosacea keratitis, and Widmark's conjunctivitis.

Medicolegal

Medical Services Necessaries of Life—Husband and Wife Liable for Them When Furnished to Minor Children

(Evans vs. Noonan and wife (Cal.), 128 Pac. R. 794)

The District Court of Appeals, Third District, California, holds that medical services are legally included among the necessaries of life and that parents are liable for them as such when furnished to their minor children. The court says that whether medical services are "necessaries of life," within the legal meaning of that term, is a question which has never been, so far as the court is advised to the contrary, presented to and decided by the courts of that state. At any rate, the court was cited to no recorded decisions in which the question has been passed on. But on principle it can imagine no reason why medical services should not be so considered. To the contrary, a ruling holding them not to be so would appeal to its mind as barbaric both in its conception and conclusion. It is not possible that any court would hold that the obligation of parents to furnish their minor children with the necessaries of life is fully satisfied when they have provided them with food, clothing and shelter, or, to state the proposition in another form, that parents would not violate their obligation to provide their minor children with the necessaries of life by refusing them requisite medical attention when ill.

The word "necessaries," as it has been applied by some of the cases in which its legal import has been interpreted, is a relative term and, as so applied, has been restricted or enlarged in the scope of its legal signification according to the circumstances and conditions of the parties. Some of the cases have held that it is not confined in its application merely to what is essential barely to support life, but that it includes many of the conveniences of refined society, such as ornaments of dress which are usually worn by persons of rank and position. In the present case, however, there was nothing which required the court to go further than to say that, under the law, it most certainly at the least means the common necessaries of life or such things as are proper and requisite for the sustenance of man. With equal certainty these include, besides food, clothing and shelter, such medical attentions in cases of illness as are absolutely requisite to relieve physical suffering and pain and to overcome or conquer disease, if by such attentions it can be done.

Medical services being counted among the necessaries of life, the court further holds that the wife is equally liable with the husband for the payment for such services when the same are rendered to and for their minor children at the request of her husband only, under the terms of section 171 of the Civil Code of California, which, as amended by the legislature of 1905, provides that: The separate property of the wife is liable for the payment of debts contracted by the husband or wife for the necessaries of life furnished to them, or either of them while they are living together, provided that the provisions of this act shall not apply to the separate property of the wife held by her at the time of her marriage or acquired by her by devise or succession after marriage.

The law applicable to the case before the court as made by the pleadings and proof was correctly stated in a requested instruction of the jury that, "in case you find from the evidence that the plaintiff at the request of either Mr. or Mrs. Noonan furnished and performed medical services and attendance to and for one of their minor children, it is the same as though the medical attendance was furnished to defendants themselves, for both parents are responsible for the care of their minor children and necessaries of life furnished to a child is deemed to have been furnished to the parents. While ordinarily a wife is not responsible for any debt of her husband, the law makes an exception in the case of necessaries of life furnished to either or both of them while they are living together as husband and wife. You are instructed that medical attendance, when furnished to a wife, husband or minor child, is deemed by law to be necessaries of life. Therefore, if you find from the evidence that at the time set forth in plaintiff's complaint the plaintiff furnished medical attendance to defendants, or either of them, or at their request to any of their minor children, and that at said times the defendants were married and living together as husband and wife, it is your duty to find for the plaintiff in whatever amount you may find from the evidence is due to him."

Validity of City Ordinance Providing for Good Inspection

(Keiper vs. City of Louisville (Ky.), 154 S. W. R. 18)

The Court of Appeals of Kentucky on a rehearing reverses a former decision dismissing the appeal, and affirms a judgment imposing a fine of $25 on the appellant Keiper for violating a city ordinance in refusing to allow a health officer to make an inspection. The ordinance was one to prevent the manufacture and sale of impure foods and provided that, "Any officer, agent or employee representing the health department, or police officer, of the city of Louisville shall at all times have right of entry for inspection to any building, premises or place of any kind where food products are stored or kept for sale, and to any wagon, railroad car or other vehicle of any kind used for the conveyance of food products to be sold in the city of Louisville; and such officer, agent or employee shall at all times have the right to inspect all apparatus, appliances, utensils or other equipment to be used in connection with the production, handling, transportation or distribution of food products to be sold or offered for sale in the city of Louisville, and such officer, agent or employee shall have the right at any time to take samples of food products therefrom for the purpose of analysis. No person, shall interfere with such health officer or with any agent employee in performance of his official duty when such person has reasonable grounds for recognizing said health officer or agent or employee in his official capacity, nor shall any person hinder, prevent or refuse to permit any inspection or examination aforesaid," etc. The court says that while, under the constitution, the people must be secure from unreasonable search, there was nothing in the record to show that an unreasonable search was imposed on the appellant. In its exercise of the police power to prevent the sale of impure foods, the city may at least provide for the inspection of such foods by a competent inspector, in places where they are offered for sale. An ordinance providing for such inspection does not violate the constitutional provision as authorizing an unreasonable search, and as there was nothing in the record to show that more than this was done, in the case before the court, it must, in the absence of a bill of exceptions, presume that the circuit court ruled correctly. If the ordinance as to the offense with which the appellant was charged was void, so far as it authorized imprisonment, that was no reason why the valid part of the ordinance should not be enforced.

Plaintiffs May be Asked if Willing to Submit to Physical Examinations—States Permitting Examinations

(Chicago, Rock Island & Pacific Railway Co. vs. Hill (Okla.), 129 Pac. R. 13)

The Supreme Court of Oklahoma holds that, in the trial of a personal injury case, on the cross-examination of the plaintiff he should be required to answer the question whether he is willing to submit to a physical examination of the injuries by reputable physicians of the community, acting under the appointment of the court. The court says that the trial court declined to permit such a question to be asked or answered. This ruling was based on the decision of the Supreme Court of the territory of Oklahoma, in *City of Kingfisher vs. Altizer*, 13 Okla. 121, holding that "the courts of this territory cannot order a plaintiff, in an action for an injury to the person, to submit to a surgical examination in advance of or during the trial of the cause." The case was correctly decided, for it followed a decision of the Supreme Court of the United States (*Union Pacific R. Co. vs. Botsford*, 141 U. S. 250), the decisions of which were controlling on the territorial court.

Whether this court would follow that rule now it does not say, because not a question here before it to decide. But it notes in passing that the courts of the following states permit such a physical examination: Alabama, Arkansas, Colorado, Georgia, Indiana, Kansas, Kentucky, Michigan, Minnesota, Missouri, Nebraska, North Dakota, Pennsylvania, Ohio, Texas, Washington and Wisconsin; in Florida, New York and New Jersey such examination is provided for by statute. In the federal courts and those of Utah, Massachusetts, Montana and South Carolina, an examination is denied.

The question before the court was, not whether a physical examination may be ordered by the court, but whether the plaintiff, on cross-examination, may be asked the question whether he is willing to submit to a physical examination, conducted by impartial physicians appointed by the court. The purpose of a cross-examination, among other things, is to test the truthfulness of the witness, and, if he is the plaintiff, his good faith, the righteousness of his case. In an action for personal injuries it is manifest that the jurors are entitled to all the information which can be produced, not only on the cause of the injuries, but also the extent of the injuries, in order to determine whether the plaintiff should recover at all, and, if so, the amount of his recovery. Would an examination of the injuries by competent and disinterested physicians, appointed by the court and acting under its supervision, aid the jury in ascertaining these facts? Manifestly it would, and the jury would doubtless rely more on the testimony of such a physician than they would on one employed as an expert by one of the interested parties. Would the plaintiff be prejudiced by such an examination? Manifestly he would not, if his case was a bona fide one, and if it was not bona fide the law should not exert itself to assist him in concealing the bad faith. Such an examination, it is manifest, would be in the interest of truth and justice. If the plaintiff declined to submit to it for good reason, he, of course, could explain his reason to the jury. If he declined to submit to it without reason, that fact would doubtless have its influence as affecting his good faith, and it seems to the court that such a question would tend to assist the court and jury in arriving at the truth and would result in no harm to any party asserting a bona fide claim.

Indeed, the very case of *City of Kingfisher vs. Altizer*, 13 Okla. 121, relied on by the plaintiff, recognizes the principle here announced; as does also the case of *Union Pacific R. Co. vs. Botsford*, 141 U. S. 250, which was followed in the Altizer case. On the authority, therefore, of the very cases which deny the right to a physical examination, this court holds that the unreasonable refusal of the plaintiff to submit to one may be considered by the jury as affecting his good faith.

Validity of Ordinance Against Having Unclean Milk Bottles

(People vs. Frudenberg (N. Y.), 140 N. Y. Supp. 17)

The First Appellate Division of the Supreme Court of New York affirms a conviction of the defendant, a driver for a milk company, of having in his possession and having received milk bottles which had not been washed after holding milk, and were unclean. The court says that the evidence would support a finding that the defendant had collected a large number of used milk bottles, some of which had not been washed, that he had taken them to a railway station at Park Avenue and One Hundred and Sixty-Fourth Street and unloaded them on the platform, where they were stacked up. About two hours later the bottles, including the unclean ones, were loaded on cars. The milk company had a cleaning plant at Manhattan Street, and the reason why the defendant did not take the bottles there was that it was out of the way. The defendant made no question as to the facts, contenting himself with attacking the constitutionality of the ordinance under which he was prosecuted, which read as follows, the part attacked being the last sentence: "It shall be the duty of all persons having in their possession bottles, cans or other receptacles containing milk or cream, which are used in the transportation and delivery of milk or cream, to clean or cause them to be cleaned immediately on emptying. No person shall use or cause or allow to be used any receptacle which is used in the transportation and delivery of milk or cream for any purpose whatsoever other than the holding of milk or cream, nor shall any person receive or have in his possession any such receptacle which has not been washed after holding milk or cream or which is unclean in any way." The defendant urged that, on a strict construction of the section, and both sides agreed it should be so construed, it was unreasonable, in that it made it an offense for the milk company to reclaim or retake its own property, if some one else had violated a duty with regard to it. The court has no doubt that this strict construction is precisely what was intended by the board of health, and it fits perfectly with the agricultural law, to which it is merely supplementary. The court is of the further opinion that the sentence objected to is not unreasonable, and is within the police power of the state. It does not deprive the milk company, the defendant's employer, of its property, but merely requires the company, before accepting a bottle or other receptacle from a customer, to insist that that customer shall observe the law and wash out the receptacle. This can be done either by ceasing to deliver milk to a customer who refuses to obey the law, or by lodging an information against the persistent law breaker. That the company had provided a sterilization plant to clean bottles and receptacles did not meet the requirements of law, especially when the bottles were not taken to the plant, but were shipped away in an unclean condition. Both the statute and the ordinance are undoubtedly drastic, but the danger to be apprehended from the use of unclean receptacles for milk intended for human food is so obvious and so well known that drastic measures to prevent the possibility of such use are reasonable and justifiable.

Right of Recovery for Services Though Not Beneficial

(Hall vs. Mooring (Ga.), 76 S. E. R. 759)

The Court of Appeals of Georgia says that this was a contest between two members of the gentler sex. The plaintiff was a practitioner of the art or science of osteopathy, and the defendant either needed, or thought she did (which was the same thing) the services of the plaintiff. Several visits were made at $3.10 per visit, the ten cents being added for street-car fare, and the whole bill amounted to $27.90. The defendant said that she paid all she really owed and that the plaintiff charged her for a number of social calls, during the course of which the defendant was importuned to continue the treatment. The defendant said that she declined to do so and that the services rendered by the plaintiff gave her no relief and were so unsatisfactory that she was forced to resort to a physician of the allopathic school, who administered pills and mixtures in the good old-fashioned way. On the issues of fact the plaintiff outswore the defendant, or at least the jury in the justice's court thought she did, and the judge of the superior court refused to interfere. This was the end of the law so far as this branch of the case was concerned. It would never do to hold that a doctor is entitled to recover only where he cures the patient. If the court did, the members of this learned profession might hesitate to respond in extreme cases where the chances were against them. So far as this court is concerned, the doctors may continue to bury their mistakes and recover for their services as they have always done. If the court were dealing with lawyers, the rule might be different. The defendant said that she ought not to pay the extra ten cents per visit because the plaintiff usually walked. The plaintiff testified, however, that the charge was usual and reasonable. If so, she had a right to walk and save the ten cents.

An Expert Has No Greater Privileges than Any Other Witness

(Dixon vs. State (Ga.), 76 S. E. R. 794)

The Court of Appeals of Georgia holds that only when expressly provided by law can the privilege of a witness resist the demand of justice for the truth and the witness refuse to answer a legal question. A physician is competent to testify as an expert and no expert can refuse to testify because he has not been compensated or will not be compensated for his testimony. An expert, testifying as a witness, has no greater privilege than any other witness.

KENTUCKY STATE MEDICAL ASSOCIATION

Sixty-Third Annual Meeting, held at Bowling Green, Sept. 2-4, 1913

The President, Dr. W. O. Roberts, Louisville, in the Chair.

Officers Elected

For the list of newly elected officers, see The Journal, Sept. 13, p. 877.

The Vaccine Treatment of Pertussis in Children

Dr. H. A. Davidson, Louisville: I have been using a vaccine made from the *Bacillus pertussis*, discovered by Bordet, in an epidemic of whooping-cough among the children of the Kentucky Children's Home. More than fifty cases developed during the epidemic. One patient had received doses of the pertussis vaccine at four-day intervals, which controlled the paroxysm fairly well, but a bronchial cough continued. One-fourth c.c. of a mixed vaccine containing *Bacillus pertussis*, 50,000,000; *Staphylococcus aureus*, 20,000,000; *Streptococcus pyogenes*, 10,000,000; *Micrococcus catarrhalis*, 30.000,000, was injected, and within twenty-four hours there was a marked change in the cough, which soon subsided.

As to the value of pertussis vaccine as a prophylactic, I can produce very little evidence. One infant 10 days old was given 1 to 3 c.c. on arrival in the home. It was afterward exposed constantly to the infection. Within a week, it developed a slight cough, not paroxysmal, which quickly subsided. She was given the doses of vaccine four days apart, first, 1 to 3 c.c.; second, 2 to 3 c.c., and third, 1 c.c. or 20,000,000. The vaccine now on the market contains 50,000,000 bacilli per cubic centimeter and relatively larger doses are given for curative effect.

Altogether in hospital and private practice I have treated about seventy cases of whooping-cough with the vaccine with uniformly good results, in many cases brilliant results.

There is practically no reaction, either local or general, following the injection of the pertussis vaccine. There is a slight reaction both local and general following the introduction of the mixed vaccine. As a rule, three doses are sufficient to cure the whooping-cough. If a cough continues after three doses, then give 1 to 4 c.c. of the mixed vaccine, and if this does not stop the cough look out for tuberculosis glands and make the tests for tuberculosis. I have had such uniformly good results from the vaccine treatment that I heartily recommend it to the general profession as the best known treatment for pertussis.

DISCUSSION

Dr. Lillian H. South, Bowling Green: Pertussis serum costs supplied by the State Board of Health of Kentucky costs $1.20, if ordered through the board. The initial dose is 25,-000,000. The treatment of whooping-cough with this serum has proved satisfactory in my hands. I have used it in two cases as a prophylactic measure. Late in the disease it is better to give a large dose.

Dr. Phillip F. Barbour, Louisville: I have been treating whooping-cough with the pertussis vaccine for nearly two years and have obtained very brilliant results in some cases. The earlier it is administered, the better the results are going to be. I have not seen such favorable results from the vaccine after the whooping has been established as I have seen when it was used before the cough had reached that stage. It would seem that the germs tend to lose their virulency or disappear early in the stage of pertussis. A culture has to be made from an organism obtained from the throat, and practically with the beginning of the whooping, in order to be able to make a culture at all. There are some cases in which the vaccine does not seem to give the results that we desire. While it is not a specific in all cases, it is the best treatment we have for this condition up to the present time. As a rule I give 50,000,000 as an initial dose, repeating the dose every fourth or fifth day.

Epidemic Anterior Poliomyelitis

Dr. Philip F. Barbour, Louisville: The treatment must be adapted to the stages of the disease. At the outset we should attempt to lessen the congestion of the cord by any means available. The application of counterirritants will bring the blood to the surface and away from the congested area. Ergot has been recommended to reduce the size of the vessels, but it does not produce a great effect. Atropin, by sending the blood to the periphery, should prove helpful enough to redden the skin. The use of electricity on the nerves and muscles offers more help and hope than any other agent. Some massage is helpful by promoting the circulation through the muscles. Strychnin and all other forms of tonics and general tonic medication should be continued. Special attention should be paid to the deformities which result from atrophy and loss of control of the muscles. Much can be accomplished by persistent insistence on the patients trying to use any muscle fibers that can be moved voluntarily.

DISCUSSION

Dr. S. L. Beard, Shelbyville: In regard to the use of strychnin in this condition. It is a disease of impaired nutrition, a bad heart with interference of the blood-pressure. The continued use of strychnin will invariably do harm. In fact, I do not know of a more dangerous drug than strychnin. Strychnin does not contract the arterioles; it expands them, and when given continuously is as dangerous as alcohol. It should be condemned most strongly. In the equalization of blood-pressure lies our greatest hope. How are we to do that? First, by systematic rest after the acute symptoms have subsided. Second, by the proper application of hydrotherapy, by proper elimination, and not too active catharsis. Let us regulate blood-pressure so as to improve the nutrition of the parts, for in that lies our greatest hope until something shall have been done along specific lines.

Dr. John J. Moren, Louisville: It has been my misfortune to see a number of cases of anterior poliomyelitis. The cases of this disease we are meeting to-day are not the same as those we met fifteen or twenty years ago. The cases of poliomyelitis to-day have sensory symptoms, and one of the characteristic features is pain at the onset along with the paralysis, and a particular characteristic I have noticed in Kentucky is that after the fever subsides there is marked hyperesthesia of the paralyzed extremity. In early cases I have used hexamethylenamin with excellent results.

Dr. A. C. L. Percefull, Louisville: Along the line of deformities occurring from infantile paralysis, I would like to utter one word of warning. Mothers are overanxious when their children have this condition, and they are willing to grasp at every straw, some of them believing that the children will go through their whole lives with a deformity. It is this anxiety on the part of the mother which leads to exaggeration of the deformity coming from infantile paralysis. This is brought about by the taking of remedies from each family that prescribes a remedy; by using this or that battery or this kind of massage. The muscles that are not paralyzed are overdeveloped and the deformity caused by the paralysis is hastened and the opposite condition results. If you can select a muscle that is paralyzed and apply the galvanic current, you may do some good.

Dr. A. M. Vance, Louisville: If you overstimulate the muscles that are left, thereby causing them to become stronger, there is a greater chance for deformity to develop. My experience is that infantile paralysis gets well through the efforts of Nature, and all the efforts we may make are wasted until it comes to the question of deformity. I do not believe in electricity nor in massage. The nerve cells are destroyed; therefore you cannot do much good. If you can put the muscles into action, you can achieve much better results.

Diagnosis and Medical Treatment of Gastric and Duodenal Ulcer

Dr. Charles G. Lucas, Louisville: Three indications are to be met: first, neutralize any excess of acid; second, prevent spasm, and third, promote healing. The first indication is met by the use of antacids, particularly magnesium oxid and bicarbonate of soda. These may be given in doses of from 10 to 30 grains, in powder form, whenever the patient begins to feel uncomfortable, repeating three or four times a day, according to the indication.

In the treatment of hemorrhage, the first requisite is absolute rest, best secured by morphin given hypodermically and repeated if necessary. The application of a light ice-bag to the epigastrium aids in the checking of the flow of blood. The use of ice-water by tube is recommended by Ewald; in this country Kaufman has been a warm advocate of lavage, believing that thorough evacuation of the contents of the stomach will do more to quiet the organ and stop the bleeding than any other measure. Internally good results have been obtained from epinephrin in repeated doses; from bismuth, in divided doses and in one large dose after lavage. Pure aluminum metal ground into powder and mixed with glycerin into an emulsion like paint, 160 grains to the dose, will almost magically stop hemorrhage from the stomach, except that coming from large vessels. Normal horse-serum has been used extensively and many favorable reports are made concerning it.

How long should an ulcer be treated? I have long been of the opinion that a patient the subject of gastric or duodenal ulcer should submit to the rest cure for at least six weeks. If at the end of that time the symptoms have disappeared or have greatly improved, it is advisable to have him resume his ordinary vocation, but under regular and careful medical observation. If, however, after the first six weeks, when the patient is up and about, he does not regain his strength as we should expect, the cure should be tried again for another six weeks, and after this we have little or no improvement and occult blood is still present in the stool, it is best to refer him to the surgeon.

Diagnosis and Indications for Operation in Gastric and Duodenal Ulcer

Dr. A. David Willmoth, Louisville: The surgeon should operate in the following cases: First, when the symptoms are long continued and do not yield to medical treatment, and particularly when profound anemia results from the repeated hemorrhage; second, to control bleeding that threatens life; third, when perforation has occurred; fourth, to treat subphrenic and other abscesses that occur as complications; fifth, to relieve constriction of the pylorus or an hourglass contraction; sixth, to relieve various indefinite symptoms, not necessarily due to the existence of the ulcer, but following the healing of one. These symptoms are generally due to adhesions which either alter the direction of the pylorus, constrict the stomach, or tie the organ down to surrounding structures.

DISCUSSION

Dr. William H. Wathen, Louisville: Medical diagnoses of gastric ulcer are more often incorrect than they are correct. Moynihan has pointed out that over 50 per cent. of cases of medical diagnoses of gastric ulcer had no ulcer at all. The pathology was found in the appendix. There is no way of knowing positively the pathology of gastric or duodenal ulcer until the abdomen is opened. It is difficult often to differentiate between gastric ulcer and appendicitis. There is often an association of appendicitis with gastric and duodenal ulcer and gall-stones, so much so that there seems to be reason to believe there is some etiologic connection. Acute ulcers, unless complications arise, are seldom surgical and they are very often of septic origin. There is no curative treatment for chronic ulcer except excision. Medical treatment may mitigate the symptoms, but it does not effect a cure. Rest, quietude of mind and body, proper diet, good hygiene and sanitation will do as much as any medical treatment.

Dr. W. W. Anderson, Newport: About a year ago I was called in consultation to see a patient who gave a history of twenty years of chronic gastric hyperacidity, six years of which gave evidence, according to the history of attacks, of ulceration, with hemorrhage, pain, and in the last six months or more there were obstructive symptoms indicating the presence of cancer, ending in perforation and death. Such things ought not to occur. More careful study and examination on the part of the man who first sees the case would be the means of saving lives in cases of this kind. I would make a plea for more exploratory incisions in doubtful cases to determine what the real trouble is. There should be more cooperation in the handling of these cases between the surgeon and internist.

Dr. J. Garland Sherrill, Louisville: I must differ from Dr. Wathen's contention that the only treatment for chronic ulcer of the stomach is excision. I will admit that the ideal treatment for this condition is the removal *in toto* of the ulcerated area, but many of these cases will show very marked improvement and permanent recovery from simple gastro-enterostomy. This is especially the case where the ulcer is large, and where the difficulties of its removal are such that the patient will be unable to withstand a more radical operation. These cases have in many instances gone on to cure. Therefore, I do not believe it is correct to claim that these cases must be subjected to the removal of the ulcer. When the ulcer can be removed surgically, it is a very desirable thing to do.

Dr. Louis Frank, Louisville: There is practically very little difference of opinion as to the line of treatment that should be carried out in chronic ulceration of the stomach. We know that these ulcers, benign though they be in the beginning, ultimately become carcinomatous. We have been taught to depend too much on laboratory diagnosis at the expense of the clinical study of the case. A careful study of the previous history of the patient extending back over years is sufficient, with the physical examination, exclusive of laboratory findings, to enable one to make a diagnosis, and then treatment will depend on judgment as to the duration of the disease.

The Prevention of Tuberculosis

Dr. Dunning S. Wilson, Louisville: The prevention of tuberculosis is not to be accomplished by antituberculosis organizations alone, no matter how excellently they may be managed. We must request the intelligent cooperation of physicians, sociologists, lawyers, employers, employees, charitable organizations, federations of men's and women's clubs, playground leagues, tenement house commissions, law makers, boards of education, public health officials, churches, and in fact every citizen of the state. The prevention of the white plague must go hand in hand with the prevention of the black plague, the prevention of hookworm, cancer, typhoid, infantile diseases, poverty, drunkenness, abortion, blindness, feeblemindedness, insanity, accidents, dishonesty, crime, crop failures and the wanton and improvident destruction of our forests, or the wasteful dissipation of our natural resources, whether by individual or corporation. Finally, the warp and woof of such a scheme must be the leaven of human kindness and a sympathy which is a motive and not an emotion.

Uterine Hemorrhage and Its Significance

Dr. R. C. McChord, Lebanon: We do not see the great majority of cases of cancer of the uterus until a slight irregular hemorrhage appears, and on investigation it is found that this condition has existed for weeks and even months. Its approach is so insidious, and the innate modesty and ignorance of women as to its dangers so great, that the so-called inoperable cancer is frequently found to exist. Women must be taught that any unusual flow of blood, which is persistent, means something, and on the first manifestation of such a condition they should apply to their physician for examination and advice. If physicians would realize that one out of every eleven women of all ages dies of cancer, and that past the age of 35 one woman out of nine would likewise perish, and at the same time consider that its early recognition is the only hope of cure, probably we would be more earnest in our endeavors to educate our clientele as to its dangers, and make them realize the significance of uterine hemorrhage.

DISCUSSION

Dr. W. W. Anderson, Newport: Uterine hemorrhage during the child-bearing period is most often due to non-malignant causes, but the fact that it is due to such causes gives us no right to presume in any individual case that the conditions are non-malignant and demands on our part the most searching care, because as Baldy of Philadelphia said a few years ago, only 2 per cent. of cases of cancer of the uterus, taking them all in all as they come to the physician, are ever permanently cured. They do not always come to the physician as early as they should, and when they do he is slow in finding out what is the matter. These patients should receive a most searching examination to determine the diagnosis and the reasons for the hemorrhage. and we should not presume it is a pelvic condition of something else.

Dr. Edward Speidel, Louisville: It is astonishing how often a hemorrhage from mucous polypi is either not diagnosed or is mistaken as a hemorrhage from cancer. Differentiation is very simple. Vaginal examination and the fact that the tumor presenting has a pedicle leading into the cervix will enable one to make the diagnosis.

Dr. Louis Frank, Louisville: We frequently make an error in looking on all cases of cancer of the uterus as cancer of the cervix. We should not forget the fact that we may have cancer of the body of the uterus in which there is no ulceration, no external manifestation which can be noted by visual examination or which may be felt by digital examination. So in these cases removal of a portion of tissue from the cervix deserves commendation. In the other type of cases the removal of a section of the cervix gives no index of what is going on. The disease is inside the cavity of the uterus. If a section is removed the microscopist should know where it comes from. The tissue should be removed in long sections so that he can examine them in this laboratory, otherwise he may make an error. In cutting sections through the glands obliquely, one will get at the bottom of some of the glands; the cells penetrate into the muscularis, and it is impossible for an expert microscopist to make an absolute diagnosis at all times. In connection with carcinoma of the cervix we must insist on women having examinations if hemorrhages recur, or if the amount of hemmorrhage exceeds the normal hemorrhages during the climacteric.

Dr. A. D. Willmoth, Louisville: In connection with this subject I want to discourage the early and indiscriminate use of the curet. It has done more harm than any instrument ever invented.

Ectopic Gestation; Diagnosis and Treatment

Dr. N. C. Witt, Franklin: Ectopic gestation is operative at any stage on the discovery of the condition; complete removal of the tube and the abnormal pregnancy by the abdominal route. Even when the patient is apparently exsanguinated, we may be enabled to tie off the bleeding points and by the intravenous injection of normal saline save a life. Or if the hemorrhage has stopped and the patient has reacted, we have no assurance that there will not be a secondary and fatal hemorrhage. Finally, if the initial clot held, its liability toward becoming infected would serve as a menace to the woman.

DISCUSSION

Dr. D. C. Donan, Jr., Morganfield: I was called in consultation to see a woman who was taken suddenly ill with the classical symptoms of internal hemorrhage. She was in severe shock. We controlled the hemorrhage by giving saline infusion before making a diagnosis, and when the patient rallied we made a vaginal examination and diagnosed the case as a ruptured ectopic pregnancy. The patient refused operation. We kept her in bed for about ten days. She had a slight relapse, complained of great pain and nausea, and concluded she would go to the hospital. We made all arrangements, but the day before we were to take the patient to the hospital she had a severe hemorrhage and died within an hour. Necropsy revealed a fetus and a gallon of blood in the peritoneal cavity.

Puerperal Eclampsia; Cause and Treatment

Dr. Edward Speidel, Louisville: I advocate surgical measures. No true progress will be made unless such surgical measures are thoroughly established. I can see no justification for cesarean section in eclampsia. If the attacks occur in the seventh or eighth month of pregnancy, then the convulsions can readily be controlled by narcotics, according to the method of Stroganoff. There is no indication for and nothing is to be gained by a hurried operative delivery. At full term a competent obstetrician will always be able to deliver the eclamptic woman through the vaginal route under normal conditions. If the condition is complicated by a contracted pelvis or obstructing tumor, then operative delivery is performed on account of these complications and not on account of the eclampsia. In cases of this kind the surgeon without obstetric experience should at least consult with an experienced obstetrician before subjecting a woman to such a formidable operation.

DISCUSSION

Dr. Virgil E. Simpson, Louisville: While I have been much interested in the advent of Abderhalden's methods of biologic tests as applied to the diagnosis of pregnancy, I feel greater concern in the therapeutic possibilities, through its application in the toxemias, and particularly that of eclampsia. In fact, as Schwartz has well said, "The diagnosis of pregnancy is only a trifling part of this work."

Abderhalden's theory is that free chorionic villi of implanted ovum induce in the maternal organism a reaction which produces digesting ferments for placental tissue.

It is not irrational to conclude that in eclampsia the formation of protective ferments is deficient, and hence intravascular digestion of placental protein is sufficiently imperfect to permit the accumulation of this blood-formed material, resulting in the symptom complex termed eclampsia.

These interesting findings suggest the possibility, in the near future, of a therapeusis with a serum from patients having large quantities of "protective ferments" or from animals so treated as to immobilize these ferments.

Vaccine Therapy

Dr. R. Hayes Davis, Louisville: Vaccines are often a useful adjunct to other treatment and will not infrequently cure a condition where other means have failed. They have a distinctly limited field and should be used only when an accurate diagnosis can be made and where they are directly indicated. Autogenous vaccines are usually preferable and should be used in most infections where possible. Vaccines should be used only by men who understand thoroughly the laws of immunity and know the dangers of improper vaccine treatment, and in acute conditions too great care cannot possibly be exercised.

Traumatic Displacement of the Kidney

Dr. J. H. Peak, Louisville: I have found by experience that the best incision is the one advocated by the Mayos. You will encounter the ileohypogastric nerve, which may sometimes be double. This nerve should not be cut because it supplies the skin over the side of the abdomen and crest of the ilium with sensation, and if injured, it will cause much pain, and if severed, the patient will complain of a peculiar numbness, sometimes for many months. The surgeon should be careful not to include this nerve in his suturing, because such an accident will cause the patient intense suffering for two or three days.

One of the most important points in the postoperative treatment is to avoid the use of opiates, as far as possible, as they produce nausea and vomiting. The bowels should be kept regular by enemata in order to avoid constipation. Enemata are much better and safer than purgatives, which often cause nausea and vomiting. The patient should be kept in a recumbent position for twenty-one days following the operation and should be cautioned against violent exercise or jarring during the period of convalescence.

5 *New Form of Apparatus for Freezing-Point Determinations. E. H. Bartley, Brooklyn.

5. Freezing-Point Determinations.—The apparatus devised by Bartley consists of a Dewar tube A, 22 cm. high and 6 cm. inside diameter, set in a wooden base. This is fitted with a rubber stopper having three holes. Into the large hole is fitted a heavy glass test-tube 20 cm. long and 3 cm. wide passing down to near the bottom of the vessel. Two other holes are for two small brass or copper tubes, one terminating just below the rubber stopper and the other passing to the bottom of the vessel and coiled around two or three times. These coils are perforated with a series of small holes. Inside of the test-tube passing through the rubber stopper is a second test-tube of about the same length and 2.5 cm. in diameter, held in place by a section of rubber tubing drawn over it and separating the two tubes by a narrow space. In operation, this space is filled with alcohol. A delicate thermometer with a platinum wire coiled loosely around its lower end completes the apparatus. In the apparatus used by the author, the stirrer is operated by a toy motor run by an ordinary dry cell. This can be dispensed with, if desired, and the stirrer operated by hand, although this mechanical contrivance makes the apparatus almost automatic.

To use the apparatus, fill the vessel about one-third full of ether or carbon disulphid. Insert the rubber stopper tightly, connect the shorter metal tube with a Richards aspirator pump, attached to the water service. The liquid to be frozen is placed in the inner test-tube. There should be enough liquid to cover the mercury bulb of the thermometer, when the latter is lowered to the bottom of the tube. The water is then started through the Richards aspirator pump, which draws air through the ether in a series of bubbles, causing it to evaporate. Owing to the well-known principle of the Dewar tube, applied in the popular thermos bottle, almost all the heat used to vaporize the ether is derived from the thin layer of alcohol between the two test-tubes and from the liquid under examination. There is no frosting of the outer vessel, the whole system remains clear and transparent and the thermometer can easily be read at all times. When the temperature reaches zero, the stirrer is started.

It will be observed that the temperature steadily sinks from —2 to —3 C. before freezing begins, that is, two or more degrees below the true freezing-point of the liquid. Then, suddenly, freezing occurs and the temperature-reading rises to a fixed point and remains there for some minutes. When this point is reached the water is shut off and an accurate reading taken. This is the freezing-point of the liquid. There is no necessity of adding ice to start the freezing as is usually done in other forms of apparatus. The whole process is automatic and all the observer need do is to regulate the flow of water running through the pump and read the thermometer. It is advisable, when the temperature reaches zero, to draw the air through the ether more slowly until freezing takes place, by partly shutting off the flow of water. The thermometer should be accurate and should easily indicate 0.5 degree. For accurate work the Beckmann adjustable thermometer should be used. The thermometer is the most important and most expensive part of the apparatus. The rest of the apparatus is cheap and can be put together from glassware kept in stock by any of the larger dealers in chemical apparatus. The amount of ether required for a determination is not over 25 c.c., and costs but a few cents.

12 Nerves and Nursing Mother. C. A. Frost, Utica, N. Y.

6. Tuberculous Adenitis.—Speaking of tuberculin, Jopson says that this is a form of therapy which will in time largely supplant surgery in the treatment of tuberculous lesions. It is a valuable adjuvant to surgical treatment in other tuberculous conditions. It may prove useful in preventing recurrence in cases in which repeated operations have been performed, and sometimes results in apparent arrest, improvement or cure when operations have been impossible or ineffectual.

10. Case of Hydrocephalus.—This case is reported by Speese because of the extensive degree of hydrocephalus present. The measurements of the head were as follows: circumference, 60 cm.; from the anterior fontanel to the posterior part of the posterior fontanel, 35 cm.; from one parietal eminence to the opposite, 31 cm.; from the top of one ear to the other, 35 cm. The lower extremities were completely paralyzed and the reflexes were absent, but wasting of the muscles was not noted. The general condition of nutrition was excellent, and the child took nourishment without trouble. The Wassermann reaction was negative. The case belonged to the congenital type, the cause of obstruction being obscure.

14. Treatment of Acute and Chronic Diarrheas.—Wilson has been treating all chronic diarrheas, and the acute diarrheas and dysenteries that resisted the ordinary treatment, with opium, bowel irrigation, etc., with a diet of spinach, turnip greens and mustard tops with the most gratifying results. It has been his custom to begin by giving a tablespoonful or more of spinach, turnip greens or mustard four times a day, continuing from one to two weeks; no other food being allowed unless patients become very anxious for it, when a little dry toast or common corn bread is given. The first few stools after beginning the diet will show the undigested food, but immediately following this the movements become normal in consistency, and usually after the second day an enema will be required to move the bowels. When there has been distention of the bowels, the flatulence disappears, and when there is tenesmus the relief is most remarkable. Wilson's first experience with this diet was confined to chronic conditions, but later he found that the same good could be accomplished in the acute dysenteries of early spring which failed to respond to the ordinary dose of salts or oil with a little opium in some form. In these acute conditions he has rarely found it necessary to give a dose of opium after beginning treatment. Spinach is prepared in the usual way, insisting on a little more thorough cooking. Turnip greens and mustard, a diet largely used in the rural districts of the South, have given the best results, but when these cannot be had, spinach answers well and is better borne by delicate stomachs. Wilson usually insists on patients continuing the use of the diet with lunch and dinner for some weeks after getting on regular diet. In two patients suffering with pellagra, the diarrhea has been entirely relieved by this diet, but others have not seemed to be benefited by it. Amebic dysentery is improved, but the cure is rarely permanent.

32 Symptomatology of Gall-Bladder Disease. H. C. Moffitt, San Francisco.

23. **Gall-Tract Disease.**—The normal gall-bladder, Cooper says, can be completely emptied by comparatively light pressure during exploratory laparotomy. If it cannot it should be assumed that there is some hindrance to the outflow. If one ligatures the common bile-duct in the dog, one can still completely empty the gall-bladder by comparatively light pressure, the bile filling up the hepatic ducts. It seems not improbable that the same might be possible in man with an acutely developing common-duct block. Whether or not with a block of some duration this would be likely to occur is another question, but it would seem wise for the surgeon in his gall-bladder work to see the course the bile takes when he squeezes the gall vesicle. Cooper emphasizes the words "light pressure," since with a block at Vater's papilla it is possible that bile could be forced into the pancreatic ducts. The outside of an organ is no real clue as to what is within. In the case of gall-bladder infection simulating malignant endocarditis that Cooper saw, the gall-bladder was not enlarged, and its outside seemed healthy to the surgeon; yet a drop of bile drawn off through a hypodermic syringe and examined microscopically was seen to teem with organisms, and the drainage of this healthy-looking gall-bladder cured the patient. In the angle between the body and neck of the gall-bladder is a lymph-node which when indurated feels not unlike a calculus. In cholycystitis the lymph-nodes up and down the common duct are found to be enlarged. Lymph-node enlargement then must not in doubtful cases be interpreted to mean a malignant condition.

28. **Intravenous Administration of Diphtheria Antitoxin.**—Mixsell asserts that the intravenous administration of antitoxin in young children, although not always easy, is perfectly safe when done with skill and care. The operation does not, as a rule, commend itself to private practice and ordinarily should be performed only under the best of conditions. There appears from a study of 158 cases to be so little clinical difference in the results obtained from the intravenous and subcutaneous exhibition of antitoxin that we are not warranted in asserting that one method is more efficacious than the other. Except in severe septic cases, therefore, and cases seen late in the disease, the subcutaneous method is to be preferred. Antitoxin given subcutaneously should be given in large initial doses.

45. **Non-Protein Nitrogen of Blood in Nephritis.**—In a series of non-nephritic individuals the total non-protein nitrogen of the blood, determined by Folin's method, was found by Farr and Austin to lie between 15 and 43 mg. per hundred c.c. From 50 to 60 per cent. of this was in the ammonia-urea fraction. In cardiovascular disease with renal congestion, but without other renal lesion, there was no evidence of increase of non-protein nitrogen in the blood, or of alteration of the ammonia-urea percentage. In chronic nephritis with marked albuminuria and edema there was very little, if any, increase or alteration. In chronic nephritis with hypertension the non-protein nitrogen was definitely increased, ranging from 40 to 180 mg. per hundred c.c. of blood. The percentage of the ammonia-urea fraction was usually higher than in non-nephritic cases. Cases showing high non-protein nitrogen values were subject to rapid fluctuations in these values in the course of a few days. As a rule, clinical improvement was associated with a fall of the non-protein nitrogen figures to nearer the normal range. Uremia was almost always accompanied by an increase of non-protein nitrogen in the blood, but no constant relation could be established between the degree of increase and the tendency to uremia. The authors' cases have not yet been followed for a long enough period to admit of conclusions as to the possible relation between the degree of non-protein nitrogen retention and ultimate prognosis. They believe this method to be a valuable aid in the clinical study of nephritis and that it can readily be carried out in any well equipped clinical laboratory.

46. **Cerebrospinal Fluid in Acute Poliomyelitis.**—The spinal fluid in the 126 cases of acute epidemic poliomyelitis examined by Fraser was usually clear and colorless and did not appear to be under any great amount of pressure. It showed changes in the number of cells present, or in the globulin content, or in both, in the majority of patients examined on the first few days after onset of symptoms. The number of cells was usually highest during the first week, and in one case reached the figure of 1,221 per cubic millimeter. The globulin reaction was usually most marked during the third week. The number of cells diminished rapidly and was above normal in only 32 per cent. of the cases in the third week. The increase in the globulin reaction persisted to the fourth week and might be present for a considerably longer period. The cell increase was due almost invariably to mononuclear

cells of various types. The lymphocytic type of cell was the most common. A high polymorphonuclear count was noted in the very early stages. All the fluids reduced Fehling's solution. The examination of the spinal fluid may be of value in diagnosis in the preparalytic stages and in abortive cases.

48. **Excretion of Glycuronic Acid in Pneumococcus Infections.**—It has been found by Medigreceanu that the amount of glycuronic acid excreted in the urine, estimated by Tollens' furfurol distillation method, is increased during the febrile period of almost all cases of lobar pneumonia in man. Patients weighing from 57 to 70 kg. excrete during the febrile period from 0.8 to 1.3 gm. of glycuronic acid in twenty-four hours, while the output of a normal individual of the same weight, age and under similar conditions would not exceed from 0.4 to 0.6 gm. This increased output is not dependent on outside factors; it is attributable to pathologic changes of the organism itself during the disease. Similar observations have been made in postpneumonic empyema and bronchopneumonia. Fasting rabbits, with general pneumococcus infection, have also shown a marked increase in the output of glycuronic acid during the pathologic process. Whether the conjugated substances with the glycuronic acid in the cases studied have the same origin and are qualitatively the same as under normal conditions, or whether we are dealing with different compounds, has not yet been determined.

49. **Histogenesis of Blood-Platelets.**—Brown believes that under normal circumstances blood-platelets are largely derived from the megakaryocyte of the blood-forming organs. The transitional leukocyte, representing a persistent form of the embryonic premegakaryocyte, is a circulating homologue of the megakaryocyte and probably plays some part in normal platelet formation. Under conditions of excessive demand for platelet production there may be a greater or less reversion to an embryonic mode of platelet formation in which less highly specialized cells than the megakaryocyte participate in platelet production. In addition to the megakaryocyte, the cells that have been observed to take part in platelet formation are hyperplastic endothelial cells in the marrow, and mononuclear and transitional cells (premegakaryocytes) in the marrow, spleen and blood.

50. **Mechanism of Growth of Connective Tissue.**—When connective-tissue cells have been cultivated for a certain length of time in a medium which has been repeatedly changed, Carrel says that a definite relation arises between the rate of growth of the cells and the composition of the medium. It is possible, by adding to the culture-medium a given quantity of certain substances such as embryonic juices, to foresee the extent to which a fragment of tissue composed of a given strain of cells will increase in a given time. The rate of growth of a strain of cells can be accelerated or retarded by the addition to the medium of activating or retarding substances. The dynamic condition of a strain of connective-tissue cells which have been living in a given medium for some time is not a definitely acquired characteristic, but a temporary state, and is the product or function of the medium in which the cells are living, and is readily modified merely by altering the composition of the medium. A knowledge of the characteristics of the growth of connective tissue described has led to a new result—the indefinite proliferation of a strain of connective-tissue cells outside of the organism. The strain of connective tissue originally obtained from a fragment of chick embryo heart, which had been pulsating *in vitro* for 104 days, was still actively alive after sixteen months of independent life, and more than 190 passages. The rate of proliferation of the connective tissue sixteen months old equaled and even exceeded that of fresh connective tissue taken from an 8-day-old embryo. It appears, therefore, that time has no effect on the tissues isolated from the organism and preserved by means of the technic described. During the sixteenth month of life *in vitro* the cells increased rapidly in number and were able in a short time to produce a large quantity of new tissue. This fact, therefore, definitely demonstrates that the tissues were not in a state of survival, as was the case in certain earlier experiments, but in a condition of real life, since the cells of which they were composed, multiplied indefinitely in the culture-medium.

51. **Action of Strychnin in Frogs.**—The main results of this investigation are summarized as follows by Githens: Doses of strychnin amounting to 0.0006 mg. per gram of frog will cause tetanus at all temperatures between 5 and 30 C. (between 41 and 86 F.), although at low temperatures the tetanus may appear late. A dose of 0.0003 mg. per gram of frog will frequently produce tetanus at 5 C. as well as at 30 or 27 C. (80.6 F.), but may nevertheless fail to produce any reaction at such an intermediary temperature as 21 C. (69.8 F.). Smaller doses, 0.0002 mg. per gram, will cause tetanus in the cold but not at high temperatures.

52. **Elimination through Mucosa of Urinary Bladder.**—Kleiner asserts that the bladder is practically impermeable for diffusible substances present in the blood in great excess even in the absence of the kidneys, the chief organs of elimination of the body.

53. **Cultivation of Parasite of Rabies.**—About fifty series of cultivations were made by Noguchi with the brain or medulla removed aseptically from rabbits, guinea-pigs and dogs infected with "street" virus, "passage" virus or "fixed" virus. Usually the animals were etherized just before spontaneous death occurred. The method that has yielded the result to be reported is similar to that employed successfully for the cultivation of the spirochetes of relapsing fever. In the cultures very minute granular and somewhat coarser pleomorphic chromatoid bodies arise which on subsequent transplantation reappear in the new cultures through many generations. The same bodies, so far as appearances are concerned, are obtained from "street," "passage," and "fixed" virus. The smallest of these bodies are just on the limit of visibility with the Zeiss apochromatic 2 mm. lens.

On four different occasions Noguchi observed in the cultures from "passage" and "fixed" virus nucleated round or oval bodies surrounded with membranes totally different from the minuter granular bodies, although arising in the cultures in which the latter occurred. Their appearance was sudden and their duration four or five days, when they diminished coincidently with an increase in granular bodies. In one of the four instances the larger bodies appeared in a culture prepared from the brain of a rabbit previously inoculated with a culture of "passage" virus which had given rise to the symptoms of rabies. In two of the instances the larger nucleated bodies arose in cultures prepared from "fixed" virus in which Negri bodies were difficult to demonstrate either in sections or in films. The cultivated nucleated bodies are actively multiplying, by division or budding, and exhibit the appearance not of bacteria but of protozoa. In size they range from about 1 to 12 microns. Under the dark-field microscope, as in the stained preparation, they show definite characters. The center is nuclear and the membrane is distinct and highly refractive. The united individuals in a multiplying mass may be enclosed for a time in a common capsule (?). By inoculating cultures containing the granular, pleomorphic or nucleated bodies, rabies has been reproduced in dogs, rabbits and guinea-pigs, as shown by the typical symptoms and positive animal inoculations; while the film preparations from the brain of the animals contained always the granular and sometimes the nucleated bodies in large numbers.

Journal of Nervous and Mental Disease, Lancaster, Pa.

August, XL, No. 8, pp. 489-550

54 *Analysis of Cerebrospinal Fluid in One Hundred and Nine Cases of Disease of Nervous System Not Including Acute Meningeal Affections. W. F. Schaller, San Francisco.
55 Piblokto or Hysteria Among Peary's Eskimos. A. A. Brill, New York.
56 *Trigeminal Dural Neuralgia. B. R. Tucker, Richmond, Va.

54. **Analysis of Cerebrospinal Fluid.**—Schaller attaches great importance to the information derived from the analysis of the cerebrospinal fluid in all cases of nervous disease in which the diagnosis appears in doubt. In his series it was exceptional that the clinical findings were at variance with the laboratory findings. This occurred in two cases of paresis, in

a case of pes planus and in one case of progressive muscular spinal atrophy. In regard to the pressure of the fluid, the globulin and cell content, his experience does not differ materially from the experience of the Hamburg school. He believes, however, that even in cases of chronic meningeal inflammation, of which the syphilitic process is a type, the estimation of the total protein is of value. Six cells per cubic millimeter appears the upper limit of normal. The Wassermann reaction in the fluid is highly characteristic of a process of syphilitic origin and, generally speaking, is of greater significance than the blood Wassermann when it is desired to establish the nature of a given nervous disorder.

Schaller agrees with Hauptmann that the positive Wassermann reaction in the larger amounts of fluid is also very characteristic of nervous syphilis. He has no case in which the clinical evidence was against the assumption of a syphilitic affection in which the fluid was negative in the smaller amounts and positive in the larger amounts. In his series of tabes cases he found the Wassermann reaction to be more frequently positive in the fluid than in the blood. This is opposed to the later view of Nonne but is in accord with the opinion of most observers. In cerebrospinal syphilis the reaction occurred more often in the blood than in the fluid. This is in accord with the original experiences of Nonne who thus sought to establish a differential point between the true syphilitic and the parasyphilitic affections, which opinion he has later modified from his experience in tabes.

56. **Trigeminal Dural Neuralgia.**—Tucker has observed in the last five years a type or variety of head pain, neuralgic in character, yielding but slightly to the usual analgesics, having more or less distinct manifestations and due, in his opinion, to neuralgia in the dural branches of the fifth nerve, just as tic douloureux, with which it is at times associated, is due to neuralgia in its peripheral branches. For this condition he has selected the name of trigeminal dural neuralgia. The cause of trigeminal dural neuralgia seems to be the same as in trifacial neuralgia, which is usually constitutional. These causes are most frequently malaria, rheumatism, diabetes, anemia, syphilis, arteriosclerosis and sometimes other general disturbances. The nature of trigeminal dural neuralgia is that it occurs in attacks of sharp, intense pain of irregular periodicity; that nausea, vomiting, flashes of light and familial tendency are not prominent features; that the pain, as a rule, is unilateral and may radiate to the face, neck or shoulders; that the pain does not yield to the usual headache remedies; that vasomotor and trophic disturbances are common; that this head pain cannot be traced to the usual causes of headache producing changes in cerebral circulation, but that it appears to be due to chronic systemic diseases like chronic rheumatism, chronic malaria or arteriosclerosis, and that remedial medication directed toward the conditions just named usually cures the dural neuralgia.

Tucker reports nine cases. Most of these patients are in middle life, a hereditary factor is practically absent, the pain is sharp and intense, the supposed cause is a chronic constitutional condition, exciting causes are variable, and radiating pains, tic douloureux and vasomotor disturbance are of common concomitance. These headaches have extended over periods of from eight months to twenty years; in frequency they vary from a few days to a few weeks and are of irregular periodicity; the attacks themselves last from a few hours to several days; the pain is usually unilateral, previous treatment has at best had only temporary effect and these cases yielded to specific medication directed to the underlying cause.

76 Case of Saccharomycetic Infection of Lungs. W. Wovschin New York.

69. **Duodenal Ulcer.**—The indications for surgical intervention in duodenal ulcer in Einhorn's opinion are as follows: 1. Perforation requires immediate operation. 2. Recurrent profuse hemorrhages (hematemesis or melena or both) endangering the life of the patient require a prophylactic interval operation. 3. Frequent small hemorrhages, not being influenced by rational treatment, leading to an appreciable degree of constant anemia, demand operative intervention. 4. Patients with constant continuous hypersecretion, accompanied by intercurrent *ischochymia*, not yielding to treatment, should likewise be operated on. 5. Severe pains, not influenced to a considerable extent by a repeated course of rational medical treatment, form a strong indication for operative measures.

71. **Results of Intravenous Injections of Extracts of Goiter on Blood-Pressure in Dog.**—The authors found that a powerful depressor substance exists in exophthalmic goiters and that a primary injection establishes tolerance to the action of further injection. Atropin does not inhibit its action The substance does not behave physiologically like cholin The action is chiefly through peripheral dilatation aided by some diminution in cardiac output. Irritability of the vagus is not decreased. The existence of a crossed tolerance between the depressor action of extracts of exophthalmic goiters and of serum from patients with exophthalmic goiter suggests that the two substances are the same.

72. **Variations of Urea Content of Blood.**—McCaskey isolates the urea by a modification of the method described by Herter. As finally worked out the technic is as follows: Five c.c. of blood are taken from an elbow vein by a syringe and poured directly into 60 c.c. of absolute alcohol contained in a suitable flask at the bedside. This is allowed to stand twenty-four hours, when it is filtered and the precipitate washed with hot distilled water. This is evaporated to dryness at moderate temperature, after which the residue, which with proper technic contains practically all of the urea, is redissolved in 5 c.c. of distilled water. The urea is then determined with a modified Hüffner apparatus by the hypobromite method. The ordinary gas-collecting tube or eudiometer for urine, which measures about 13 mm. in diameter, is much too large to measure the gas from the minute quantities of urea found in the blood, so that McCaskey had a special tube made about 4 mm. inside diameter and graduated in 0.01 c.c. One c.c. of gas forms a column about 10 cm. long, representing 0.056 (1/18 per cent.) of urea. This is about the high normal limit, but 0.01 c.c. of gas can be measured and this would be equal to about 0.00056 per cent. The total length of the tube is such that percentages up to 0.5 could be determined, and such relatively large quantities of urea in the blood are very rare.

91. **Foundation of Education.**—The manner of learning, says Mulford, should begin early, but—teaching, formal teaching, should not. The brain is not ready for real thought before its eighth year, and so, anything requiring thought should be barred until then. Before that we have the primitive brain to consider, and the primitive brain itself considers *only* action. There should be no *formal* schooling for a child under 7 years of age, but the foundation of its education should be begun. That is, we should lay down the right pathways, not forgetting that these pathways come through action. The child under that age should have an active life, but it should be action that is under proper direction. He should not be thrust out into the back yard or on the street to pick up things for himself, mostly undesirable things; his activities should be so directed that he will learn useful things through them. The little child comes into knowledge of the external world through intimate association with it, through contact. That which he learns he learns unconsciously, without effort, and as a matter of fact through constant and everyday association with it. He learns to say "Mamma" through hearing the word many times, day after day. The impulse reaches his brain through the afferent nerve fibers, and, after a sufficient number of these impulses have been received, the motor centers controlling the muscles having to do with speech awake to the consciousness of the word, and, acting on that consciousness, the muscles coordinate and pronounce the word. But, even after the word is pronounced, the centers are not in immediate control of it; their control is not perfect at the first attempt, nor yet at the second. The word impulse is so complicated that it requires many repetitions before it is learned. This, Mulford continues, should be the manner of the acquisition of knowledge by the very young; in that manner should the foundation of an education be laid. Children under 8 years of age should learn, but learning should not be forced on them. The process must be made interesting and understandable from their point of view. Most children, at any age, learn with difficulty under the ordinary school routine, and usually have to be driven to their books. That is because, first, they do not begin in the right way, and, second, because the work is not presented so that they may grasp it. If these children learn anything at all, it is only through sheer memorizing of facts. But it is not the memorizing of bare facts, facts that only are to be repeated parrotlike, that constitutes education. Education is the individual, and, more than the individual; it is the present and the future, the individual and the world. It is the welfare of both that is determined by the foundation of the individual's education, by the development of the child's growing brain.

97. **Gastro-Intestinal Intoxication.**—During the past three years, Manion attended three cases, all fatal, the outstanding features of which were a very acute onset of so severe an intoxication as to cause coma, absolute constipation, vomiting of black material, and death in from one to three days. The constipation was so absolute and the vomiting so intractable as to resemble an obstruction of the bowels, but the antemortem findings in one case, and the post-mortem findings in the other two, revealed no sign of organic obstruction, but only a paralysis of a certain portion of the small intestine, above and below which the bowel was absolutely normal. Despite the fact that the material in the distended, paralyzed portion of bowel could easily be forced in either direction, Nature, even with the assistance of oil, salts, and so forth, was quite unable to overcome the obstruction caused by this paralysis; with the result that the distended portion acted as a reservoir of toxins from which the body absorbed enough poisonous materials to cause ultimately a fatal ending. Taking into account the gravity of this condition, Manion suggests that the treatment should consist of interstitial injections, stimulants, irrigation of bowel and stomach, and strong purgation. But if it were found impossible to satisfactorily evacuate the bowels of the patient, it is the opinion of Manion that a laparotomy would be indicated with the object of forming an artificial anus to drain the distended portion of bowel, which is nothing more or less than a toxic reservoir, absorption from which is gradually killing the patient. The whole operation could be done inside of ten minutes without even the shock of an anesthetic if the patient were unconscious, as he usually is in this condition. And the artificial anus could be attended to after recovery from the acute condition.

100. **Treatment of Puerperal Eclampsia.**—Zinke has formulated the following definite plan of treatment for puerperal eclampsia: If the patient has or has had convulsive seizures, 25 drops (15 m. or 1 c.c.) of tincture of veratrum viridi are given hypodermically, and repeated every hour until the pulse is reduced to 60 per minute or less. If within an hour the pulse falls from 150 to 100 per minute only from 10 to 15 drops are injected in the succeeding dose. More than two or three injections are rarely necessary to bring the pulse down to 60. This is the most valuable remedy in the treatment of eclampsia. A copious enema of soap-water serves to wash out the large intestine. The catheter is employed to empty the bladder; the urine is measured and examined. As soon as the patient is able to swallow, a tablespoonful of Epsom salt, or some other saline cathartic, is administered per mouth. Stronger cathartics are given only when the saline proves ineffectual. (By this time, if the patient is not in a hospital, she should, if possible, be taken to one.) Whether the patient is in a hospital or not, immediately after the foregoing treatment has been administered she is given a hot bath or hot pack, preferably the former. Neither the bath nor pack exceeds half an hour in duration. The patient is then rubbed dry and placed in a warm, dry bed. The bath or pack is given not oftener than twice in one day. Ordinarily but one bath or pack is necessary in twenty-four hours.

The only food is milk or broth or both. Water or Fischer's solution may be administered freely. The latter may be given by rectum, or, if the case be an urgent one, intravenously. Chloral, by mouth or rectum, is given if the patient is very restless. Of late Zinke has discarded the use of chloroform and morphin; ether or gas-ether is the anesthetic of choice if operative measures must be employed. If the patient is at the end of the first stage of labor, and then only if the symptoms are grave, forceps may be employed to terminate labor. If the first stage is not complete, or if labor has not begun and the patient has improved under the treatment before mentioned, the case is then left to Nature until the first stage of labor is completed, when forceps may be applied. In cases of anemia, or asthenia from any cause, the normal saline solution or Fischer's solution is given by rectum or intravenously.

With very little variation this has been Zinke's plan of treatment for the last ten years, during which time thirty cases of eclampsia were observed. Four mothers died, 13.3 per cent. Fifteen of the children, 50 per cent., were lost. It is not asserted by Zinke that this mode of procedure will be invariably successful, but his experience impels him to believe that in those cases in which it fails very little could have been expected from surgical intervention. The good results obtained from strictly medical care in these cases far exceed the results accruing from all the surgical means proposed for the relief from this disease.

British Journal of Children's Diseases, London

August, X, No. 116, pp. 337-384

1 *Hereditary Congenital Torticollis. D. M. Greig.
2 Two Cases of Ateliosis. F. P. Weber.
3 Two Successful Cases of Operation for Strangulated Inguinal Hernia in Female Infants of Ages of 22 and 17 Days. R. H. A. Whitelocke.
4 Refraction Work in School Children. J. Allan.

1. **Hereditary Congenital Torticollis.**—The family cited by Greig consists of father, mother and four children, two of each sex. The children's maternal grandmother had a left congenital wry-neck. The mother, an only child, aged 35 years, is the subject of a left congenital wry-neck for which no treatment has ever been attempted. The head inclines to the left, the left ear being approximated to the left shoulder and the face looks toward the right shoulder. The sternomastoid muscles are well developed, though the left is more prominent than the right and the trapezii muscles are not abnormal. The degree of torticollis is slight. She can put her head perfectly straight and without effort, but as soon as her attention to the position is relaxed, her head invariably inclines again toward the left. The father is a normally developed man of the artisan class, perhaps slightly undersized, but healthy. The eldest child is a daughter, aged 10 years, strong, well developed and without peculiarity.

The second child is also a daughter, aged 7 years, but she has a left congenital wry-neck, more marked and obvious than her mother's. The wry-neck in this child was not noticed until she was 6 months old. She had had no illnesses previous to that time, and has had no illness of importance since. Even after the deformity had been admitted its extent was not appreciated until quite recently, when, the child having fallen and cut her head, her hair was shorn to facilitate dressing; the deformity naturally became much more noticeable. There is marked contraction and prominence of the left sternomastoid muscle; the left suboccipital area seems very empty while the right seems fuller than normal, and this fulness appears to be due in great part to the cervical spine, which presents a dextroconvex scoliosis. Otherwise the child is of good physical and of normal mental development and is getting on well at school. The third child, a boy, aged 5 years, is strong, well and healthy, and free from defect. The youngest child is 2 years of age. He has a very marked left congenital wry-neck, presenting conditions exactly similar to those of his sister in appearance and in every detail, however trifling.

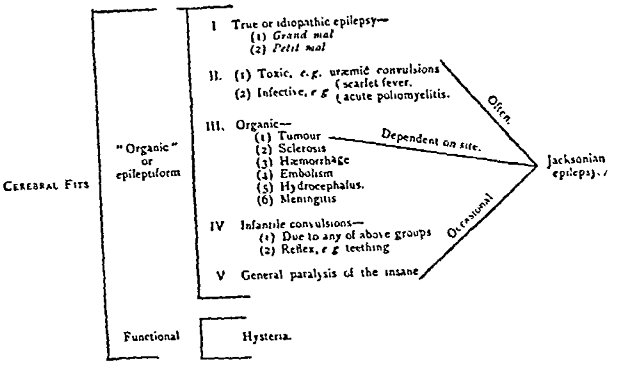
11. **Surgical Cases.**—Power cites: (1) foreign body in the esophagus; (2) pneumonia simulating abdominal inflammation; (3) acute duodenal perforation simulating pneumonia;

(4) multiple infection of tongue and glands; (5) recurrent spontaneous hemorrhage into the breast (hemophilia?); (6) spontaneous fracture of the thigh secondary to cancer of the uterus.

14. **Surgical Cases.**—Corner cites a case of sarcoma of the femur in a boy 12 years old; a case of granuloma of the jaws; one of tuberculous mediastinal abscess; one of spastic diplegia, Little's disease; deformities after arthrectomy, and two cases of hernia, one with a movable testicle.

18. **Three Cases of "Fits."**—Fleming makes use of the following table in speaking of the pathology of these cases:



CEREBRAL FITS
"Organic" or epileptiform
I True or idiopathic epilepsy—
(1) Grand mal
(2) Petit mal
II. (1) Toxic, e.g. uræmic convulsions
(2) Infective, e.g. scarlet fever. acute poliomyelitis.
III. Organic—
(1) Tumour
(2) Sclerosis
(3) Hæmorrhage
(4) Embolism
(5) Hydrocephalus.
(6) Meningitis
IV Infantile convulsions—
(1) Due to any of above groups
(2) Reflex, e.g. teething
V General paralysis of the insane
Often.
Dependent on site.
Occasional
Jacksonian epilepsy.
Functional
Hysteria.

20 *Recognition and Treatment of True Idiopathic Epilepsy in Children. J. N. G. Nolan.
21 *Treatment of Dysentery by Injection of Emetine Hydrochlorid. J. H. Thompson.

20. **Idiopathic Epilepsy in Children.**—The management of the child should be based on general hygienic and dietetic lines. Regulated periods of exercise and instruction must alternate with regular periods of rest and repose in Nolan's judgment. Corporal punishment must be absolutely prohibited. All over-exertion and strain, whether mental or physical, must be assiduously guarded against. The usual stimulating dietary of tea and meat had better be abolished, and milk and cereals substituted. Drug treatment had better be avoided at this stage, save the administration of general tonics and necessary aperients. A carefully-regulated life with a purin-free diet and a small daily dose of bromids is the treatment par excellence. The bromids do not require to be given in great quantities or at intervals during the day. The smallest dose which appears to exert a favorable influence over the fits should be taken as the maximum, and this never should exceed 60 grains. The effect is intensified by the full quantity being given at one time. The best time is at night or before rising, depending on whether the patient is subject to diurnal or nocturnal attacks. Plenty of water should be given with the dose, and sufficient laxative to insure a daily evacuation of the bowels. The best adjuvant is the syrup of Virginian prune.

21. **Treatment of Dysentery.**—Thompson's treatment usually was to start off with ʒvi of castor oil and a few minims of tincture of opium; after that had produced its effect he ordered mxx tincture of opium in ℥ss of water, to be followed fifteen minutes later by 30 grains of powdered ipecac, in emulsion. (No food having been taken for some time previously.) This was repeated every four hours. Diet restricted to soup, milk, or albumin water, and the patient rigorously confined to bed. If, after twelve doses there was no improvement Thompson then ordered the saline treatment—

		gm. or c.c.			
℞	Sodii sulphatis	4	66	or	ʒ i
	Acidi sulphurici dil.				♏ x
	Aquae ....ad	16			℥ ss

Misce. Sig. Such a dose every two hours.

This was given till blood and mucus had disappeared from the stool.

Later he resorted to emetine hydrochlorid. First he gave small doses, 1/3 grain, but now he never uses less than ½ grain doses for adults, and sometimes when he gets early cases he injects 1 grain, which practically aborts the disease. He has never found any ill effect following an injection. In mixed dysentery infection—i. e., amebic and bacillary—Thompson finds that injections of emetine, and ℥ss doses of the acid sodium sulphate mixture by the mouth is the most satisfactory method, strict attention always being paid to diet and rest. He has treated about 150 patients with emetine hydrochlorid. In some of these the treatment had no effect whatever, and those, according to Rogers, are of bacillary origin. So, therefore, not only does emetine cure the amebic variety (which constitutes about 85 per cent. of the dysentery in Thompson's district), but it serves for a differential diagnosis for bacillary dysentery, and thus enables it to be quickly treated along the proper lines.

24 *Operation for Prolapse Complicated by Hypertrophy of Cervix. W. E. Fothergill.
25 Hemorrhages into Angiomatous Fibromyoma of Uterus and Atheroma of Uterine Arteries. W. F. Shaw.

23. **Sequelae of Labor.**—Examining 543 primiparae sixteen days after labor, Solomons found that cervical laceration after normal labor is very common, occurring 219 times in this series. If it occurs, and hemorrhage is present, immediate suture should be practiced: if no hemorrhage, the tear should be sewn in two months, or else a routine examination should be made of all women at the end of their child-bearing period, when all lacerated cervices should be repaired. Postpartum retroversion of the uterus, when not fixed back by inflammation, is caused by the dorsal decubitus. The best treatment, therefore, is postural. Solomons urges that every patient should be examined once a month for at least four months after confinement. When non-union of a stitched perineum occurs, a second perineorrhaphy should be done immediately in aseptic cases. Solomons says that no definite dictum can be laid down about early rising until some more statistics are published. In normal clean cases postural treatment and gymnastic exercises are advised.

24. **Operation for Prolapse Complicated by Hypertrophy of Cervix.**—Fothergill uses a single incision for both the amputation of the cervix and the excision of the redundant vaginal wall and has found the results more satisfactory than those obtained by doing the operations separately. The cervical canal is dilated and a circular incision is made round the cervix with a knife. The vaginal wall, the bladder and the parametria are then snipped free with scissors and pushed back from the cervix. The vaginal wall is next incised for an inch or so on either side of the circular incision already made, the new cuts extending directly to the right and to the left. The anterior vaginal wall is now separated from the parametric tissues and from the bladder, and a triangular portion with its apex near the urethral aperture is cut away. The cervix is next amputated, enough being cut away to leave the uterus 3 inches long. The stump of the cervix is now stitched into the posterior part of the incision. The first suture brings together the central point of the posterior limb of the vaginal incision and the mucosa lining the posterior wall of the cervical canal. The second and third stitches unite vaginal wall and cervical mucosa right and left of the first. And so on, until the sides of the vaginal incision come together in front of the stump of the cervix. By this time the newly constructed os is beginning to disappear upward and backward. The lateral edges of the vaginal wound with the subjacent connective tissue are brought together in the middle line from behind forward. The line of suture disappears from view as the later sutures are tied. The perineum is finally repaired as before. Fothergill finds this method of operating convenient both when the elongation of the cervix is mainly supravaginal and also when the elongation mainly affects the vaginal portion.

29 *Investigations into Relationship of Tarbagan (Mongolian Marmot) to Plague. G. E. Tuck.
30 *Presence of Acetone Bodies in Urine and Their Clinical Significance. J. E. Piper.

26. **Tuberculin Treatment.**—Tuberculin treatment in Mackenzie's opinion is still on its trial. The results of it so far are not brilliant, certainly not convincing. Vaccine treatment, as a whole, is on its trial, and if we except staphylococcus infections, Mackenzie says no more can be said for vaccines than for tuberculin. He has never seen a person who has been cured by vaccines of anything of which he could not get well without. He has yet to see absolute convincing proof that tuberculin treatment by itself will arrest or cure or improve a larger number of cases than would have arrived at the same results without the treatment. Until we have that we must preserve an open mind on the matter. The fact is that tuberculin as a remedy, if it is a remedy, must be put on a far lower plane than many remedies which we possess for the treatment of disease. The most that can be claimed for tuberculin is that it promotes the natural defenses of the body. That is something, but the same can be claimed for fresh air, for good food, for hygiene, for care, for climate, and for all the other weapons which we possess.

Much, in Mackenzie's opinion, remains to be done to prove that tuberculin possesses any very high value as a remedy. Let it be shown, he says, that tuberculous disease in animals can be cured more readily or arrested by means of tuberculin treatment than without. For a number of years Mackenzie used tuberculin in a large number of cases. He has used extract and endoplasm. He has given it orally and subcutaneously and at longer and shorter intervals. He has given it in repeated small doses and in gradually increasing doses. He has used it, he says, because he felt it ought to have a full trial. But after all the trials he has made he still feels uncertain as to the value of tuberculin.

29. **Relationship of Tarbagan to Plague.**—Even though the tarbagan occasionally suffers from plague, Tuck says, the epizootic is never extensive, and the animal does not play nearly so important a rôle in the spread of plague as does the rat. Indeed, its direct relationship to human plague may be considered negligible. Moreover, the mode of living and habits of the tarbagan are very different from those of the rat; for example, while the rat is a more or less domestic creature in close contact with man, the tarbagan is the reverse.

30. **Acetone Bodies in Urine.**—In his ward work Piper found that an attack of pain in the pelvis or abdomen, such as a mild attack of appendicitis or salpingitis, will produce diaceturia. If the attack passes away the diacetic acid will be eliminated in a few days and will disappear at once if pancreatin be administered. If the pain persists, or reappears at short intervals, the diaceturia will persist in spite of the pancreatin, although it will be greatly lessened thereby. If the pain becomes more acute the patient will commence to vomit. The urine of the patient is now examined, and the examiner will say that either the vomiting is due to the acetone or the acetone is due to the vomiting. The suggestion that the error in metabolism was occurring earlier and that oxybutyric acid was exerted instead of acetone is refuted by the fact that diacetic acid will react at a dilution of 1 in 120,000, and surely this percentage at least would be present if oxybutyric acid was formed.

In treating these patients Piper has followed out the two common methods of treating diaceturia as well as one of his own. He treated only patients who had no acetonuria before operation when comparing the three methods, viz., treatment by sodium bicarbonate, by glucose, and by pancreatin—and he found that sodium bicarbonate had little or no effect, that glucose had an appreciable effect, but was simply dwarfed out of existence by the pancreatin. He gave 25 grains again as soon as possible after the operation, and in only one case out of a large number did he find any acetone present, and then only a trace. It is quite possible, he says, that this patient did not get all the pancreatin ordered. In cases of preanesthetic acetonuria, measured quantitatively, he found the amount diminished after operation under this treatment. He tested the pancreatin in all cases and found that it digested starch, although in some cases the process was slow. There was no carbohydrate in the stomach or intestine for it to break down, as the patient had had the usual starvation preparation. To effect this strong and undoubted reaction it must be absorbed in the blood; but what does it do then?

33. **Origin of Leukocyte.**—McCulloch holds that leukocytes are in no sense of the term blood-cells, and that the expression "white blood-cells" is a misleading anomaly. He believes that they are a part of the lymphoid system.

38. **Chronic Mediastinitis.**—There are two conditions in Lian's opinion in which energetic treatment of mediastinitis is to be instituted. 1. In presence of syphilitic mediastinitis intensive treatment is called for, either with soluble mercurial salts, especially the cyanid of mercury, by the intravenous method, or with insoluble salts (especially calomel) or the arsenicals in prudent doses. The influence of the treatment is remarkable at the period of gummatous infiltration and that of invasion of the mediastinum; it is less efficacious when the mediastinitis is fully constituted. 2. In mediastinopericarditis freeing the heart by Brauer's method has yielded good results in some instances. It is indicated in cases of mediastinitis with pluricostal systolic retraction at the apex if the myocardium is not exhausted. In tuberculous mediastinitis we have recourse to general antituberculous measures, but in most cases we shall only be able to employ palliative means and first and foremost patient must be placed at rest under hygienic conditions of life, because this alone often has an excellent influence.

50. The Anaerobes in Typhoid Fever.—Melikov has found in the stools of typhoid patients a bacterium which he thinks has not been previously described, an anaerobe; he calls it the satellite bacillus. He never found it in any but typhoid stools, and he believes that it is responsible in a large part for the intestinal lesions in typhoid. He conceives of typhoid as a syndrome combining two distinct processes, one of the septicemic type, due to the action of the true typhoid bacillus which lives in the general circulation or in the blood-producing organs; the other, a process of necrosis, occurring exclusively in the portions of the intestines which contain no air, due to the action of a strictly anaerobic, powerfully proteolytic bacillus, the *B. satellitis.* Usually these two processes develop together, both microbes associated in the intestines; then one or the other gets the upper hand and we have the toxic element predominating or the intestinal element.

53. Spirochetes in the Brain in General Paresis.—Examination of the brain of nine persons who had died from cerebral hemorrhage from one to fourteen months after the onset of progressive paralysis showed spirochetes in all but one case. In all the positive cases the men had succumbed to a cerebral hemorrhage. In three cases the spirochetes were as numerous as in a primary lesion. See also Editorial, page 776.

57 Apparatus for Inhalation of Chloroform. (Nouvel appareil pour l'anesthésie chloroformique.) P. Fredet.

56. Ligation of Hypogastric Artery in Abdominal Hysterectomy.—Proust and Maurer used to ligate the hypogastric artery only when the women were corpulent or other conditions rendered the hysterectomy unusually difficult. But it proved to have so many advantages that they now do it systematically as the first routine step. It facilitates the search for the ureter, shortens the operation as a whole, reduces the loss of blood, and facilitates the removal of the uterus. In order to obtain all these advantages the hypogastric must be ligated beyond the ureter, not inside of it, the ureter being drawn inward out of the way. The ligature is applied to the hypogastric artery not through a separate incision in the peritoneum, but in the upper part of the principal incision, and the point where it is applied must be at farthest not over 2 cm. from the bifurcation. They give seven large illustrations showing the exact technic as they have applied it in eight cases of uterine cancer.

59 Case of Mesenteric Thrombosis. G. Drouin and A. Parcelier.
60 Care of Surgical Instruments. (Des soins à donner aux instruments de chirurgie.) W. Dubreuilh.

58. Poisoning from Anilin Dyes in Footwear.—In one case a healthy young man wore a pair of russet shoes which had been dyed black and were still not quite dry. In two hours he became livid, with extreme cyanosis, the lips bluish, the ears purple, the nostrils retracted; the respiration was 29, the pulse, small but regular, was 120 and the skin was chilly, but there was no nausea, dizziness, syncope or tendency to collapse. The urine was blackish but none passed after the first hour. The discovery of the newly blackened shoes in a corner of the room where the young man had tossed them on his return home in the above condition, three hours after he had put them on, cleared up the diagnosis. The symptoms soon subsided. In a second case the young man had put on the newly dyed shoes without socks and started out on his bicycle. In fifteen minutes he was seized with nausea, and fell in a syncope from his wheel. He was picked up in serious collapse with intense cyanosis of the face, respiration 42, pulse filiform, the heart sounds dull. After four hours he passed a blackish urine and in another hour the symptoms began to abate but the weakness persisted for three days, during which period the young man was incapable of the least physical or mental effort. Creyx' third patient was a woman who grew pale and dizzy during the afternoon on several occasions. She went at once to bed each time and the symptoms subsided. She finally discovered that the attacks coincided with the wearing of green stockings, and they never recurred after she had discarded these stockings. In 1910 Landouzy reported ten cases of similar poisoning from russet shoes dyed black, all in children. He experimented on rabbits and found that the intact skin readily absorbs the anilin dyes; the animals died when absorption was through an opening in the skin. Heat favors the absorption. Mongour in 1908 reported a case in which the symptoms from the poisoning proved severe and lasted a long time. Creyx comments on the rarity of such phenomena considering the common use of the anilin dyes. The shoemaker who had dyed the shoes in the first case he reports stated that he had used the same dye on hundreds of other shoes, in his own family among others, and never a suggestion of trouble had been noted among the other users. The dye consisted of anilin black in anilin oil. The bibliography on the subject is appended.

70 *The Prognosis. (Le pronostic médical. Ses méthodes—son évolution—ses limites.) A. Chauffard.

62. Weakness of the Pulse.—Martinet's extensive research on the connection between the viscosity of the blood and the blood-pressure was summarized in these columns May 31, 1913, p. 1746. If the blood is less fluid than normal while the blood-pressure is normal or below normal, the pulse will be persistingly weak. This hyposphyxia syndrome, as he calls the persisting weakness of the pulse, is characterized by a tendency to cold hands and feet, congestion in the liver, varices, and various subjective cardiovascular disturbances. Insufficiency of certain of the ductless glands is a contributing or causal factor, helping to maintain a vicious circle. In the present article he outlines the treatment which, he declares, is both rational and effectual. The trouble is not a morbid entity but merely a process of pathologic physiology, a functional disturbance and not a lesion, and the aim is to correct or compensate the defective functioning, gradually leading the organs involved back to normal functioning. The first step is to stimulate the circulation, and for this we have (1) drugs, strychnin and spartein, epinephrin or hypophysis extract, given separately, associated or alternating; (2) muscular exercise, ranging from friction, massage and passive exercises, active movements in the reclining position, gymnastic exercises with elastic resistance, up to walking and climbing; (3) subcutaneous injection of oxygen, which, he says, has a marked stimulating influence on the circulation while the viscosity of the blood declines. The subcutaneous injection of oxygen is the most powerful means at our command, he reiterates, to act on hyposphyxia.

The digestion is almost invariably defective in patients of this class, and systematic stimulation of the digestive glands is an important factor in treatment. His method for this is to have the reclining patient half an hour before meals take a wineglassful of tepid Vichy water and twenty minutes later a few drops of some bitter stomachic. This prepares the stomach for the meal and stimulates the gastric glands. During the meal the patient takes a little of some good preparation of pepsin and two hours after the meal a tepid aromatic infusion of pancreatic and duodenal extracts, including the trypsin, diastase and steapsin. This organotherapy is to be brief; it only aims to tide the patient along until the glands do their work properly. If kept up too long it would be injurious as it might deaden the secretion reflexes. He thinks it is advisable to alternate the subcutaneous epinephrin and hypophysis extract treatment with ovarian and thyroid treatment, individualizing according to the indications and the responses to the various measures applied.

To the objection that the above represents a very complicated course of treatment, he replies that the trouble that is being treated is very complex. It requires systematic permanent measures, alternating transient measures, plus various accessory measures. After ten days he changes from the subcutaneous stimulants for the cardiovascular system (strychnin, spartein, epinephrin, hypophysis extract) to the pluriglandular organotherapy and back again, keeping up for several weeks the measures to act on the digestion or until they are no longer needed. Besides the oxygen, or in its place, iodin or arsenic may also prove useful. Treatment along these lines has restored many patients to complete health when before for months or years their vitality had been at a very low ebb and nothing seemed able to lift them out of their debility. In one case a thin, weak woman of 30 had a differential blood-pressure of 1.5; viscosity 5.2, and extreme atony of the stomach and bowels. She gained 22 pounds in five months and 11 more by the end of the year under this treatment, while the differential pressure rose to 4.5; the viscosity dropped to 4.5, and her digestion became normal. She has resumed an active life and regards her present condition as a resurrection.

When the hyposphyxia is congenital and due to general imperfect development of organs, adults are improved but not to such an extent as is liable under other conditions; but children develop under it into more normal conditions. For three women patients the above course of treatment did not bring the expected improvement and the Wassermann test disclosed the unsuspected fact that syphilis was probably responsible in these cases for the disturbances.

63. **Local Measures in Treatment of Diphtheria.**—Ménard reports research in which he found that diphtheria antitoxin seems to be a particularly favorable culture medium for diphtheria bacilli. Both in the test-tube and in animals, the bacilli thrived particularly well in a number of makes of antitoxin. He found it possible to cultivate the diphtheria bacilli for months in the antitoxin, although they lose some of their virulence and some of their staining properties. The facts observed indicate the necessity for the use of local disinfectants as adjuvants to general antitoxin treatment in diphtheria.

67. **Autoplastic Regeneration of Tissues to Close Defects.**—Morestin gives a number of illustrations to show the fine results that can be attained in the healing of a wound in the bend of the elbow or thigh or back of the knee if the limb is fastened in such a way as to coaptate the tissues enough to close the gap. Sound, healthy tissue does not retract and cause deformity; it is the cicatricial tissue that distorts. Consequently if the sound tissues can be brought so close together that there is no place left for cicatricial tissue to develop, the wound will heal without the slightest retraction and the healthy skin will stretch in time to restore perfect functioning, once the lips of the wound have been soldered together by linear healing. One of his illustrations shows a vast defect left by excision of a lesion in the front of the elbow. By bending the arm until the wrist nearly touched the shoulder, it was possible to coaptate the lips of the wound, and it healed with a linear scar. When the healing was complete it proved an easy matter to gradually stretch the skin by extending the arm a little more each day, until its full use was restored. This idea of applying hyperflexion to the region seems to be contrary to all we have been taught in respect to the healing of defects in the skin over joints, but experience is proving the correctness of his premises and the advantages of this method of preventing deforming cicatrization after burns and other lesions leaving extensive loss of substance. He reports six cases to illustrate the advantages of the method. One of the patients was a young woman and the large defect was on the back of the shoulder. The arm was twisted backward and immobilized in that position. This permitted coaptation of the lips of the wound and healing with a linear scar scarcely to be detected in the illustration. The skin is now healthy, supple and movable over the entire shoulder.

72 Partial Atrophy of the Shoulder Muscles in Erb's Juvenile Myopathy. F. Rose.

71. **Subcutaneous Symphyseotomy.**—De Bovis reviews what has been written on this subject, emphasizing that the pelvis is not permanently enlarged by the operation. The amazing simplicity of the subcutaneous technic, the aseptic conditions and the freedom from complications and mishaps, will render this operation the one of choice in management of contracted pelvis if time confirms its advantages and if no tendency to prolapse of the bladder is left. The operation is of too recent date as yet to guarantee against a possible tendency later to prolapse of the bladder in the cleft.

78 Diagnostic Significance for Cancer of Special Form of Diarrhea. (Zur diagnostische Bewertung der "Spritzer" genannten diarrhoischen Entleerungen.) G. Graul.

73. **Test for Absorption of Fat.**—Neumann states that it is possible to trace the absorption of fat in the gastro-intestinal tract by the appearance of fat in the blood. Of the various methods for determining the presence of fat in the blood he thinks the simplest, easiest and most reliable, as it certainly is the most rapid, is the examination of the blood with the ultra-microscope, the dark field illumination. He examined the blood in this way from 120 patients after abstention from fat for a day and the next morning a test-meal of a roll, butter and tea. The blood was then examined at hour inter-

vals. Sometimes in an hour after the test-meal the blood showed the particles of fat; normally the number of the fat particles in the blood rapidly increases for a time and then rapidly subsides. The fat in the blood represents the complicated work of the gastro-intestinal tract in secretion, motor functioning and absorption. If the motor functioning can be estimated separately, then it is easy to determine the actual value of the two other factors. If motor functioning and secretion are normal and yet no fat appears in the blood after the normal period, the absorbing function must be at fault. He gives the blood-fat findings as compared with the roentgenoscopic findings in six cases, emphasizing anew in conclusion the advantages of this method of testing the function of absorption in the digestive tract.

75. **Urobilin from Diagnostic Standpoint.** — Hildebrandt declares that estimation of the urobilin in the urine, stool, bile, in exudates and in transudates has great significance both qualitative and quantitative. The aim should be, he says, to determine the amount of total urobilin, including all its precursors; there is no sense in estimating separately the urobilin and the urobilinogen. He oxidates all the urobilinogen present in the fluid to be examined, transforming it into urobilin. He gives the technic with which this is easily accomplished in twenty-four hours, and warns that the test for *urobilinogen* is liable to prove misleading unless it is applied immediately after the urine has been voided.

77. **Influence of Albumin on Regeneration of the Blood.**— Hopmann concludes from his research that the albumin in the food is the normal stimulator of the new production of red corpuscles. The more albumin in the food the more reds are destroyed and the more new ones produced. He says that each gram of nitrogen ingested corresponds to about that same amount of reds destroyed and newly produced. Too much albumin in the food fatigues or exhausts the blood-producing organs, and he is convinced that this is the cause of many forms of anemia. In anemia and also when too many reds are being produced, the intake of albumin should be restricted to the limit at which there is neither abnormally high or abnormally low elimination of pigment. He adds that the danger of excessive intake of albumin in chronic and acute anemias consists on the one hand in further exhaustion of the sources of the reds in the red bone marrow and on the other hand the albumin modifies the epithelium. This entails a constitutional anomaly which he regards as the cause for the development of malignant tumors. He gives the tabulated details of the metabolic findings in five cases to sustain these views, showing the influence of ingestion of a given amount of meat. The effect of the albumin on the epithelium he estimated by the amount of epithelium thrown off on a certain area in the back and in the urogenital canal under given conditions.

85 *Fatal Postoperative Pulmonary Embolism. (Studien über obturierende Lungenembolie als postoperative Todesursache.) G. Petren

79. **Fat as Filling for Bone Cavities.**—Klopfer gives an illustrated description of eight cases in which he filled up the cavity left after excision of an extensive osteomyelitic or tuberculous focus in a long bone or bone of the face. The implant heals in place without complications in an aseptic cavity. It heals likewise in place in an infected cavity, but a fistula is liable to develop, delaying healing a little. In the three aseptic cases healing was complete in seventeen, twenty-eight and sixty days. The others still had a small fistula when healing was otherwise complete. The fat implant seemed to shorten the time required for the healing, and the after-care was much simplified by the immediate suture of the wound thus rendered possible. The subcutaneous adipose tissue was taken from thigh or buttocks, aiming to fill the bone cavity entirely, thus tamponing it with the fat tissue so there would be *no hemorrhage.* The size of the flap ranged from 1.5 to 20 cm. in length by 2 or 4 cm. in width. In two of the infectious cases some particles of fat were expelled through the fistula. It is too soon to pass definite judgment on the method but Klopfer's *impressions to date* are quite favorable.

81. **Radioscopic Sign of Dislocation of the Semilunar Cartilage.**—Instead of the normal even light space between the articulating surfaces, they are *seen to* be in close contact on the affected side and spread farther apart than normal on the *other side. Investigation* shows that the internal semilunar cartilage has been pushed entirely out of place, possibly up into the space between the condyles. When roentgenoscopy reveals this shortening of the gap and subluxation of the meniscus it calls at once for restoration of the meniscus to its proper place. Three cases in which this was successfully done are reported.

85. **Fatal Postoperative Pulmonary Embolism.** — Petren reviews the fifty-seven cases of fatal pulmonary embolism at Lund during 1897-1911; all but twelve followed an operation. He compares the details of these cases with 439 fatal postoperative cases that have been reported from various clinics during the last fifteen years. The majority followed abdominal operations: thirty-eight in his forty-five cases and 366 in the 439 on record. It is remarkable that operations on the head, limbs and upper thorax are so seldom followed by embolism. He tabulates all this material under a number of *headings and summarizes his own cases.* The figures show that fatal pulmonary embolism occurs in about 1 per cent. of all operations for *uterine myoma and cancer; only half* as often, 0.5 per cent., after other laparotomies, and only 0.3 per cent. after appendectomy. Age and sex do not seem to influence its incidence, nor the general condition as a rule, although changes in the cardiovascular system evidently cooperate. But it has sometimes occurred in robust, sound patients after an insignificant herniotomy. In half of his own cases the thrombus developed first in an iliac or hypogastric vein and generally on the left side. In six appendicitis cases the primary thrombus was in the left hypogastric vein in five; in none of the appendicitis cases was the thrombus on the right side. The evidence seems to show that the primary thrombus is rarely directly connected with the field of operation; scarcely ever with the *surgical laparotomies*, only exceptionally after hernia, bladder and perineum operations and in less than half of the gynecologic laparotomies.

In his own experience two-thirds of the fatalities occurred between the fourth and fourteenth days after the operation; three puerperal cases the eighth and ninth days, and four the thirteenth to the twentieth. If there are no signs of pulmonary infarct or embolism during *the first two* weeks, the chances are against its developing later. Petren's experience indicates further that slight fever without discoverable cause should warn of impending thrombosis. In 20 per cent. of his cases, straining at stool, change of position in changing dressings, driving in a cab, or other physical strain could be incriminated in bringing on the embolism. In the *other* cases no contributing cause could be discovered. Infection is comparatively rarely a factor. The main factors, he thinks, are defective composition of the blood and poor circulation and heart action. These factors should be combated in prophylaxis, improving the blood, stimulating the heart, preventing loss of blood and promoting the circulation by active and passive exercises of the legs in bed, change of position and light massage of the legs. In only seven of his total fifty-seven cases were conditions such that operative extraction of the embolus could have been applied with any chance of success.

87. **Hemolytic Jaundice.**—Strauss reports a case in which the chronic acholuric jaundice was associated with severe gout of the familial type. In another case the hemolytic jaundice in a man of 31, had existed since the age of 12 when it developed after pneumonia. All his brothers and sisters had had jaundice at birth. This is the only case in Strauss' experience in which the spleen was not enlarged. Lereboullet found no changes in the spleen and liver in four of his twenty cases of simple chronic jaundice. In the others the spleen alone was enlarged in five cases, the liver alone in three and in eight both were abnormal. Strauss emphasizes the importance of learning to distinguish between the cases in which the spleen is involved in the production of the trouble and those in which the enlargement of the spleen is merely secondary. Possibly Umber's sign of a splenotoxic destruction of albumin may prove the clue when complicated metabolic research is possible. He gives the findings in the above cases with considerable experimental research. In some of the cases there could be no doubt that the spleen was acting as a kind of slaughter-house for red corpuscles.

In four of his six cases there was pronounced habitus asthenicus. The combination with gout in one case suggests that possibly cholesterin might be used in treatment of the hemolytic tendency, but the experiences to date with cholesterin treatment of severe anemia have not given encouraging results. In another case the blood-producing apparatus seemed to have become exhausted after a gastric hemorrhage from an ulcer, and nearly three years later the anemia was still marked without signs of regeneration of the blood. The hemoglobin ranged from 21 to 29 and no therapeutic measures seemed to influence it, not even thorium. In a case of myelogenous leukemia in a previously healthy man of 60, the leukocytes dropped from 271,000 to 151,000 under forty-five days of benzol treatment. Then two intravenous injections of thorium were given with a three weeks' interval and the whites dropped to 62,000 while the spleen subsided in size.

88. **Palpation of the Gastro-Intestinal Tract.**—Hausmann has made a special study for years of this subject, and states that it is thus possible to map out the different parts of the digestive tract all except the loops of the small intestine. The main point in this topographic sliding and deep palpation is to avoid force. The palpation must be applied gradually and insidiously, proceeding rhythmically, synchronously with the breathing, during the phase of expiration, when the abdominal walls are relaxed. During inspiration the finger must keep still. It is impossible to palpate in this way unconscious patients as they do not breathe normally. By observing scrupulously this principle of stopping all palpation during inspiration, there is no danger of injuring the abdominal walls; the finger tip irritates the abdominal walls only when it manipulates them when they are stretched. The aim is to outline the organ lengthwise and then palpate transversely across it. An organ which we are unable to distinguish from its surroundings, and thus cannot feel, becomes evident to the sense of touch when it slides out from under the finger. The palpation is done systematically from right to left and from above downward. The stomach and large intestine are most readily palpable and being fastened at both ends can be easily located. The interpretation of the findings is facilitated by the preceding palpation of the kidneys, liver and spleen to aid in mapping out the palpation findings. With this topographic palpation displacements and tumors can be located with ease by the practiced fingers, and it often renders Roentgen-ray examination superfluous. Among the interesting points he has learned by this method is that the epigastric pain of an ulcer is due to tenderness in the spine behind, below the greater curvature, and it occurs not only with ulcer but with visceral neuroses and gall-stones. As a rule, he says, tender points are seldom useful in diagnosis of a lesion in an organ unless they can be compared with a symmetrical point on the other side. Tenderness on one side is more liable to be due to some organ; on both sides to some neurosis. Pain at McBurney's point is in reality due to irritation of the psoas muscle or nerves or lymphatics lying on it. This muscle can be made more prominent by lifting the leg, extended at the knee. Tenderness at different segments of the psoas shows whether the trouble is in the kidney region or in the region of the genitals or of the appendix. It is characteristic for the kidney region that the upper part of the psoas is tender as well as the lower. Spontaneous movability of the stomach, etc., is easily revealed by this deep palpation. The necropsy findings may fail to confirm the findings during life owing to this spontaneous movability of organs.

99 Source of Error in Bacteriologic Technic. (Eine Fehlerquelle bei der Antiforminmethode.) A. v. Lehmann.

92. **Dietetic Treatment of Constipation and Diarrhea.**—Strauss excludes from this discussion of the subject the cases in which the trouble is a weakness in defecation. He is convinced that spastic conditions are frequently responsible for constipation but that they usually have some local lesion as a contributing or causal factor. Another factor of great importance is the special segment of the intestine involved. In twenty-nine cases of chronic constipation, he found isolated stagnation of feces in the cecum in six; in the rectum and sigmoid flexure in eleven, and in the colon in twelve. These different localizations require different diets. Stagnation in the cecum requires a diet free from cellulose. Stagnation at the sigmoid flexure is scarcely amenable to dietetic measures. The aim in treatment of constipation is to stimulate peristalsis and increase the water content of the feces. The former indication is met by apple sauce, and other stewed fruits, fruit juices and fruit jellies; they act mainly by inducing carbohydrate fermentation in the intestines. Also buttermilk, sour milk, whey and the free use of lactose to sweeten lemonades, etc., honey and levulose. A certain amount of fat, especially in the form of tart sauces, mayonnaise, etc., seems to influence peristalsis favorably. To increase the water content of the feces, jellies made of agar are particularly useful. He rinses 5 gm. of agar in cold water, then soaks it in hot water and boils it in 400 c.c. of water until it is clear, then strains through gauze and flavors with white wine, sugar and lemon peel, coffee, chocolate cream or egg yolk and sets aside to cool. Much ballast makes greater demands on the work of the intestines; it is better therefore in dietetic treatment to aim rather at increasing the fluid content of the stool. In some cases a glass of cold water fasting, in others coffee or smoking may stimulate peristalsis, and these factors should not be neglected. In some cases, especially those with a neurotic element, abstention from meat for a time may be useful. With chronic diarrhea the diet should be arranged to spare the intestines as much as possible but one must be aware of the danger of not giving sufficient nourishment. Of fundamental importance in chronic diarrhea is the preparation of the food,

thorough cooking and straining through a hair sieve. It must not be forgotten that patients with a tendency to diarrhea are peculiarly sensitive to cold, even in the food. With alternating constipation and diarrhea, treatment should generally be addressed to the former. When the trouble in the intestines is located in the small intestine, control of the stool is indispensable as a guide to diet. The least error in the diet here is liable to bring on a relapse which will undo in a few days all that has been gained in months of treatment. On the whole, dietetic treatment of chronic diarrhea is a difficult task but in many cases results are highly gratifying. In few fields of dietetics are the results of individualization so unmistakable as here.

94. **Thrombosis of the Splenic and Portal Vein.**—Goldmann's patient was a man of 28, with symptoms suggesting Banti's disease—gastric hemorrhages and anemia at first and later the typical Banti syndrome. Necropsy revealed thrombosis of the portal and splenic vein traced to endocarditis with an infarct in the spleen nine years before the fatal outcome.

95. **Non-Gonorrheal Ophthalmia Neonatorum.**—Sussmann examined seventy-two infants with ophthalmia and found twenty-four cases in which the Prowazek-Halberstädter inclusion bodies were found in the conjunctival secretion; in two cases there was mixed infection with gonococci. The incubation period in twenty cases was two days in one, five days in one, six days in two, from seven to nine days in fourteen, fourteen days in one and fifteen days in one. The inclusion-bodies virus has therefore a longer incubation than the gonococcus, and it is probable that all the tardy cases of ophthalmia neonatorum are due to this cause. The secretion also differs from that with the gonococci, there is more tendency to hemorrhage, the course is more protracted and the cornea remains intact. Simple catarrh of the conjunctiva in the newborn is not of this character. He was not able to detect any connection between the cases and the trachoma of adults.

97. **Non-Gonorrheal Orchitis and Epididymitis.**—Stroink encountered several cases last year of inflammation of the testicle, primary or secondary to parotitis. By puncture and cultivation of the germs found he was able to obtain material for vaccine therapy. He also thus established that the *Bacillus fluorescens non liquefaciens* is able to set up disease of this kind.

98. **Late Injury of the Skin and Internal Organs after Roentgenotherapy.**—Schmidt warns that the new era of intensive dosage of the hard rays is liable to be followed by a crop of serious injuries of the deep organs as well as of the skin. He thinks the method is scarcely justified except for inoperable cancer of the cervix. He knows of instances in which after application of large doses of the hard rays, even filtered, after an interval of months up to a year and a half from the close of the Roentgen-ray treatment ulceration developed without there having been any erythema at the time or atrophy of the skin later. Irritation from without and unfavorable conditions for the circulation, as in the leg, favor the tardy ulceration and there is a possibility of trouble from this source in the deep-lying organs.

102. **Dread Neuroses and Vasomotor Disturbances.**—Flatau's patients were all women in the two groups he here describes. In the first group the neurosis developed with accompanying urticaria, dyspnea, palpitations and dermography. The hands and finger joints and later the knee swelled up with the dread neurosis in one case, in addition to or alternating with urticaria. In the other group the dread neurosis was accompanied by morbid blushing and a feeling of inability to speak. The neurotic dread comes first, then the blushing and in one case nausea and retching, and afterward there is headache. In both groups a few applications of hypnosis brought material relief or a complete cure. The intermittent swelling of the knee still persists in the one case.

109. **Dependence of Kidney Functioning on the Nervous System.**—Jungmann reports research on rabbits inducing experimental polyuria by puncture of the fourth ventricle. He found that the amount of urine increased sometimes to three times what it had been before the puncture and this polyuria lasted for twelve or twenty-four hours. The proportion of sodium chlorid in the urine also increased regularly, in some instances up to ten times what it had been beforehand. His tests showed further that not the mere incision of the fourth ventricle nor the general anesthesia alone or together induced the above changes in the urine secretion; they did not develop until the puncture had been made through the ventricle into the fascicle of nerve-fiber to the side of the mesial sulcus. The change in the urine secretion occurred irrespective of whether the animals were given much or very little water during the period of the experiments. The animals lost in weight from the elimination of the water. The drying out of the body could be traced by the findings with the refractometer applied to the blood. Immediately after the puncture the blood became diluted, but as the polyuria progressed it became condensed. The blood never showed a larger proportion of sodium chlorid even when the percentage in the urine was markedly increased. The same effect followed each time the puncture was repeated, but the puncture had no effect unless it was made at the special "puncture point" on either side. Severing the splanchnic nerve seemed to have the same effect as the puncture, polyuria and increased output of sodium chlorid following in the same proportions. The puncture produced no effect if the splanchnic nerve had already been divided on both sides. The research confirms the importance of the nervous system in the matter of kidney functioning and that the splanchnic nerve conveys the impulse from the brain to the kidneys.

112. **Diabetes Insipidus.**—Benario reports seven cases which confirm the importance of the Wassermann test as clearing up the etiology of diabetes insipidus; specific treatment as for syphilis soon cured all the morbid manifestations. Polydipsia and polyuria as symptoms accompanying cerebral syphilis have long been known, especially syphilitic lesions in the intermediate part of the hypophysis. This part of the hypophysis seems to have a direct diuretic action. Gummatous tumors in the hypophysis, especially in the posterior lobe, evidently are capable of inducing diabetes insipidus. The development, retrogression under specific treatment and other

changes in these gummatous tumors readily explain the variability of the diabetes picture, and also the inefficacy of treatment if sclerotic changes have already become installed. Gummatous processes in the nasopharyngeal cavity are particularly liable to spread backward to the sella turcica and the hypophysis. With polyuria in the tertiary phase of syphilis, traces of destructive processes in the nasopharynx are common. In every case of diabetes insipidus, therefore, acquired or inherited, syphilis should be suspected even in the absence of any history or signs of it. Examination of the blood and of the cerebrospinal fluid by the Wassermann technic will aid in the differentiation.

113. **Prophylaxis of Peritonitis.**—Weber writes from the clinic in charge of Döderlein to extol the advantages in threatening cases of thorough rinsing out of the abdominal cavity with twenty-five or thirty quarts of physiologic salt solution at 40 C. (104 F.) under general anesthesia. This is done rapidly, the pelvis lowered to the utmost, rinsing out all the recesses and crevices and sopping up with sponges all the superfluous fluid. Then 30 c.c. of tepid 10 per cent. camphorated oil are poured in and distributed with swabs. In 200 cases in which these measures were applied, no injurious consequences could be discovered, while the outcome was satisfactory beyond all anticipations. The method is described here in connection with a case of impalement; a young woman sliding down a hayrick slid on the handle of a buried rake and it entered the vagina and abdomen for twelve or fourteen inches. A long wagon ride was necessary before the girl reached the hospital. The laparotomy next day showed that none of the viscera seemed to be injured. The abdominal cavity was rinsed as above described, the pelvis low, and after washing out quantities of blood the fluid finally came away clear, showing that there was no persisting hemorrhage anywhere. Then the camphorated oil was poured in and spread around, the tear in the peritoneum below the ovary sutured and smooth recovery followed.

115. **Operative Treatment of Chronic Edema.**—The Journal, Jan. 25, 1913, p. 328, described Kondoleon's method of treating chronic edema and elephantiasis by opening a communication between the deep and the superficial lymphatics. Boecker here reports a case of chronic edema in which he operated on the same principle. The patient was a woman of 58 who had had one breast removed on account of cancer, and the arm on this side swelled afterward until the upper arm measured 15 inches in circumference, the forearm over 13 and the hand nearly 13. He made an incision in the back of the arm 8 inches long, under local anesthesia, and cut out a patch of fascia 6 inches long by 1.5 inches wide, suturing the wound at once. By the end of a week the edema began to go down and become softer and although now, two months later, there is still considerable edema, yet it is soft and the woman can use her hand and is able to knit.

123 Inflammation-Inhibiting Action of Epinephrin. (Zur entzündungshemmenden Wirkung subkutaner Adrenalininjektionen.) F. Gaisböck.

118. **Vascular Reflexes.**—The vascular reflexes were tested in the research reported not only in healthy persons but in several with sclerodermia, advanced arteriosclerosis and syringomyelia. Among the interesting points thus learned is the fact that irritation applied to the skin is liable to entail a vasodilating reflex in conditions which apparently exclude participation of the spinal reflex arc.

121. **Diphtheria Following Piercing the Ears.**—An infant had its ears pierced and [illegible] developed a local diphtheric process in the outer ears and also in the lungs, soon proving fatal. Necropsy disclosed that the throat was entirely free from the diphtheritic process.

126 *Operation for Varices with Minute Incisions. (Operation der Varicen mit kleinsten Schnitten.) Holfelder.
127 Pathogenese of Hydrocele. D. G. Zesas.

124. **Fascia Flaps for Patching and Supporting Organs and Walls.**—Henschen writes from the surgical clinic in charge of Sauerbruch to report the successful outcome of extensive experimental research with implants of sheets of fascia to close large defects in the wall of the chest, in the diaphragm and in the pericardium, done under differential atmospheric pressure. He found it possible thus to close a large defect in the diaphragm, working through the pleura, and is confident that the same technic can be applied even with greater ease in the clinic.

Cordua reports the successful use of a broad strip of fascia to suspend the kidney in case of wandering kidney. The method differs from Kocher's technic in that Cordua passes the strip of fascia through the capsule of the kidney, tunneling under the capsule for about half the width of the kidney. This holds the strip in place without the necessity for sutures. The fascia sling thus provided can be fastened to a rib or muscle or aponeurosis as most convenient.

Göbell uses a narrow strip of fascia passed through the transverse and oblique muscles about 2 cm. above their lower margin to reenforce the closure of the canal in operating on a femoral hernia. The muscles are thus dragged down to below the canal and both ends of the fascia strip are then sutured together as they meet after one has been passed besides through the pectineal fascia.

126. **Minute Incisions for Operative Treatment of Varices.**—Holfelder outlines with a stain on the skin the most protruding veins as the patient stands. Then he gives a general anesthetic and expels the blood from the limb and makes incisions not over 1 or 2 cm. along the vein, and exposes and carefully isolates the vein, stripping it entirely free from all clinging tissue. The vein is then severed between two ligatures and the stump is seized with a clamp and carefully wound up on the clamp until the vein tears across. The technic is like that with which Thiersch pulls out a nerve. Holfelder has succeeded in thus pulling out strips of vein totalling on both legs 80 cm. in length. He says that the intima rolls inward as the vein tears, and thus there is no fear of after-hemorrhage and the tiny incisions can be closed at once. He merely ligates the central stump of the saphenous vein in the thigh and pulls out the distal stump alone. In some cases the operation on the leg alone answered the purpose, leaving the thigh intact.

134 Advantages of Incision from Spine to Spine of the Pubis for the Alexander-Adams Operation; Fifteen Cases. (Alexander-Adams mit Tuberkulumschnitt.) G. Zickel.

128. **Clinical Importance of Abderhalden's Method of Serodiagnosis.**—Mayer declares that the contradictory findings reported by some experimenters with Abderhalden's technic are due to the fact that practitioners as a rule are not used to the painstaking exactness of chemically pure methods, and consequently conflicting results are merely because some imperfection has crept into the technic. With increased care and practice, the conflicting findings grow less and less frequent. The clinical importance is obvious of this serodiagnosis of pregnancy at its earliest inception and also after all other signs of it have subsided, as after abortion. In a case described, the suspicion of a recent abortion apparently was not confirmed by the scrapings of the uterus, but the serodiagnosis was positive. Renewed examination of the scrapings finally revealed decidua tissue. The reaction is positive with an extra-uterine as with a normal pregnancy, but it becomes negative in both after the tissues specially connected with the pregnancy have lost their vitality from the death of the fetus. Mayer reports further research with the test as applied in eclampsia and various complications of pregnancy. The response shows that the protective ferments involved keep constant, like the behavior of the blood. The response to the test also throws light on the functioning of the glands with an internal secretion, as also on metabolic disturbances and on cancer, as he illustrates with cases from his own experience. He suggests further that it may prove interesting to study racial differences in the reaction to the biologic tests.

129. **Venesection in Eclampsia.**—Less states that twenty-four of twenty-six women recovered under the ordinary measures; two were spontaneously delivered, the rest required active intervention. Among the patients were some with from twelve to forty seizures. Two of the patients succumbed. In another group of twenty-two cases venesection was applied, withdrawing from 250 to 1,200 c.c. of blood followed by saline infusion. Two in this group died also. One patient had no further seizures after the venesection; delivery occurred eight hours later. Three with eclampsia after delivery had only one seizure each after the venesection. The benefit seemed striking in another case of puerperal eclampsia. None of the women died whose eclampsia did not develop until after delivery.

130. **Artificial Stretching of the Perineum During Delivery.**—Rudolph calls attention to the reflex contractions of the uterus which occur when the perineum is stretched. The head of the fetus striking the perineum sets up vigorous contractions of the uterus by this reflex action; it is started also by introduction of the curet into the uterus. To induce the contraction when the fetal head is unable to reach down to the perineum or when the labor pains are growing weak from any cause, he introduces into the vagina his forefinger and middle finger pressed together and then spreads them apart sideways and presses them backward, stretching the perineal portion of the vulva and massaging it lightly at the same time. The uterus responds at once with contractions and the procedure has enabled him to get along without forceps in a number of cases in which their use otherwise would have been indispensable. The stretching and mobilizing of the perineum in this way materially facilitates the passage of the fetal head when it comes along, as the perineal tissues are rendered more elastic and the parturient is thus saved considerable physical stress and pain. He has not always been able to avoid the necessity for side laceration or incision, but he always knew the cases in which this was impending as the tissues refused to yield to his stretching.

136. **New Infection or Superinfection with Syphilis?**—Mariani tabulates the details of four cases from his own practice at Pavia and of twenty-six from the literature in which an apparently primary syphilitic lesion developed from a few months to several years after the actual primary infection. Some date from before the discovery of salvarsan; in some cases there had been mercurial or salvarsan treatment or both, in others no treatment had been applied. In MacDonald's case there had been scant mercurial treatment after which six years passed without any manifestations or therapeutic measures. Then an apparently primary syphilitic lesion developed near the scar from the first, on the corona. In Mariani's own cases salvarsan had been given to each patient and the interval was from four months to two years. He discusses the various theories advanced to explain such eventualities, classifying the cases according as a new cycle of the specific infection developed or as either of the cycles was incomplete.

149. **The Dry Test-Meal.**—Van Spanje calls attention to the advantages of a dry test-meal, saying that triscuit seems to be particularly adapted for a test-meal without fluids. It is put up in packages of twenty-four biscuits each and is made of the whole wheat flour. The gastric juice has no or very little influence on it. This test-meal has several advantages over others, as the exact amount of gastric juice can be estimated, because no liquids are given with it.

157. **Daily Paroxysms of Pain as Sign of Uterine Cancer.**—Greife reports a case which sustains the diagnostic importance of "Simpson's pains" as stated recently in The Journal, Sept. 14, 1912, p. 908. His patient was an unmarried woman of 50, healthy until April, 1912, when she began to have paroxysms of pain every afternoon and later also in the evening. The pains were very severe, starting in the lower abdomen and radiating down into the legs, not relieved by heat or cold, the paroxysm lasting about four hours on an average at first and later from five to six hours, with no let-up except under morphin. Nothing could be found to explain the pains until palpation through the rectum revealed a tumor in the uterus, supposed to be a myoma. On account of the intact hymen, supravaginal amputation of the uterus was done by a laparotomy. On opening the excised uterus two days later it was found filled with a cancerous growth. The abdomen was opened again in two or three weeks and the rest of the uterus then cut out. The patient was relieved from the first of all pain and has been in good health since.

162. **Medicolegal Examination of Seminal Stains.**—This article states that the rectangular and pointed crystals obtained with the Florence reagent are not so characteristic of seminal fluid as the ovoid crystals which occur singly or in groups. These ovoid crystals were discovered simultaneously last year by De Dominicis and Baecchi not only with the Florence reagent but with Dragendorf's. By modifying the Florence reagent a little these ovoid crystals show up much better, and Lecha-Marzo and Conejero are convinced that the round and ovoid crystals are the only ones for which the seminal fluid is directly responsible, the rectangular and pointed crystals being crystals of the decomposition products of lecithin, as Richter has pointed out. Their reagent is like the Florence only that it contains more iodin: Potassium iodid 1 gm.; iodin 0.5 gm.; distilled water, 25 gm. The Mangini reagent used in testing alkaloids also shows up the crystals unusually well. A microscope of only 500 diameter power is ample for the purpose.

164. **Urochromogen in the Urine.**—Vitri regards Weiss' permanganate test for urochromogen in the urine as an important aid in the diagnosis and especially in the prognosis of tuberculosis. He has applied the test to 150 tuberculous patients; the reaction is slight or absent in extrapulmonary tuberculous lesions but in acute pulmonary tuberculosis it is almost invariably positive, while it is negative during the first stage of tuberculosis running a chronic course. Of thirty-two tuberculous patients who gave a decided positive reaction, fourteen have died since, while only three have died of the fifty-six giving a negative response to repeated applications of the test, and of these three two died from an intercurrent disease. Weiss says that the urochromogen is the substance which gives the diazo reaction or its precursor, but according to Vitri's experience the urochromogen test is more sensitive than the diazo. The findings paralleled each other with the two tests in forty-eight cases, but in six others the urochromogen test was positive while the other was negative. He never obtained a positive diazo with a negative urochromogen reaction.

The findings were also remarkably concordant with the urochromogen test and the skin tuberculin test. In twenty-three cases the skin tuberculin test elicited a very slight or no response, the body evidently being incapable of a pronounced reaction, and in these cases the urochromogen reaction was always very pronounced and thirteen in this group have died since. In forty-three other cases the skin tuberculin reaction was very pronounced, while the urochromogen reaction was slight or negative, and the prognosis was comparatively favorable in all these cases. In nine cases both reactions were pronounced but the favorable outlook suggested by the pronounced response to the skin tuberculin test was not realized; in fact, eight of the patients died not long after as the pronounced response to the urochromogen test had foretold. In only four of the total cases were the urochromogen findings misleading. The urochromogen test is applied by filling a test-tube to one-third with the urine to be examined. It is then diluted with twice its volume of water, and well mixed. Half of the fluid is then poured into a second tube of the same size, and to one of the tubes are added three drops of a 1 per cent. solution of potassium permanganate in distilled water. The tube is then shaken to mix the contents. A yellow tint appears in case of a positive response as the two tubes are compared. A little sugar, albumin or urobilin in the urine does not interfere with the reaction.

165 *The Wassermann Test Applied to the Cadaver. (Betydningen af Wassermanns Reaktion, anstillet paa Ligblod.) H. Boas *and H. Eiken.*

165. **The Wassermann Test Applied to the Cadaver.**—Boas and Eiken state that the usual technic applied to the cadaver gives unreliable findings as numbers of positive responses are obtained when there is nothing to suggest syphilis otherwise. By reducing the dose to half the ordinary amount, namely 0.1 c.c. instead of 0.2 c.c., the reaction becomes much more reliable. Only three out of 326 controls gave a positive reaction with this technic. Negative findings in the cadaver are less significant than negative findings in the clinic. They obtained a negative reaction in five of twenty-nine cases of untreated active syphilis.

OZONE: ITS BACTERICIDAL, PHYSIOLOGIC AND DEODORIZING ACTION [*]

EDWIN O. JORDAN, PH.D.
AND
A. J. CARLSON, PH.D.
CHICAGO

THE BACTERICIDAL ACTION OF OZONE

The use of ozone as a gaseous disinfectant has often been advocated, but the claims made for its efficiency have little or no experimental basis. [Review of earlier investigation omitted.]

Our own experiments have been carried out (1) to determine the germicidal action of ozone on pure cultures under the conditions commonly used in testing disinfectants, and (2) to determine the effect of ozone on the ordinary air bacteria.

All experiments were carried out in a small room of about 26 cubic meters. There was one door and one window in the room. In the first experiment there was ventilation to the room through a 3-inch hole in the window. In the remaining experiments there was no ventilation, the air being worked over and over.

The ozone generator described later was placed at one side of the room about 4 feet from the floor, and was run at high speed throughout the experiments.

Analysis of the products coming direct from the ozonator showed no oxids of nitrogen present in 10 liters (quarts) of the air.

An analysis was made of the products coming direct from the machine while running at the two different speeds. Speed 1 showed a concentration of 3.5 parts of ozone per million; speed 2 showed a concentration of 8.9 parts of ozone per million.

Staphylococcus pyogenes aureus and *Bacillus pyocyaneus* were the organisms used in each experiment, being taken in each case from a twenty-four-hour broth-culture. Equal parts of litmus milk and peptone broth were used in determining the growth of the organisms after exposure.

EXPERIMENTS

EXPERIMENT 1.—Sterile cotton threads 1 inch in length were immersed in twenty-four-hour broth-cultures and then placed in envelopes. One-half the number of threads were allowed to dry for two hours at ordinary room temperature before exposure, while the other half were exposed in a moist condition. Small pieces of each thread were retained and used as controls. No inhibitory effects were visible. [Table 1 omitted.]

EXPERIMENT 2.—The organisms were exposed for periods of one and one-half hours, three hours and four and one-half hours, respectively. Only moist bacteria were used. They were exposed in Petri dishes on strips of filter-paper immersed in the twenty-four-hour broth-culture. No inhibitory effects could be seen in any of the exposures. [Table 2 omitted.]

EXPERIMENT 3.—The organisms were exposed in both dry and moist condition, on threads in envelopes and on filter-paper in Petri dishes. The first twenty-four of these experiments or tests were carried out on filter-paper. Part of the organisms exposed were dried in an incubator at 37.5 C. (99.5 F.). The last twenty-four of these experiments were carried on similarly to the first half, but with threads in envelopes. [Table 3 omitted.]

All tests in this experiment showed no effects of the ozone. No difference could be detected between the growth of those organisms at the highest concentration of ozone after long exposure, and those exposed for the short period and at the lower concentration.

EXPERIMENT 4.—Small pieces of sterile filter-paper were immersed in the broth-cultures and half of them allowed to dry for two hours in an incubator at 36.7 C. (98.06 F.). At the end of two hours small pieces were retained as controls, while both moist and dry strips of paper were exposed to the ozonator products in small cheese-cloth sacs for varying periods of time and in different positions.

The only difference in this experiment from those preceding is that *B. pyocyaneus*, dry, showed no growth after twenty-four hours of incubation at 37 C. (98.6 F.). At forty-eight hours, however, there existed no difference between this culture and the others. [Table 4 omitted.]

EXPERIMENT 5.—The organisms were exposed in the cheese-cloth sacs as in Experiment 4. The results were practically the same as in the preceding experiment.

Those organisms exposed for the longest time were placed in the position in which the concentration of the ozone was 8.9 parts per million, and here no inhibitory effects could be detected. [Table 5 omitted.]

EXPERIMENT 6.—Only moist bacteria were exposed on filter-paper for a period of three hours.[*] An analysis was made after two hours of the ozone coming ino the room, and 4.06 parts per million were found, while at three hours there were 4.5 parts present. [Table 6 omitted.]

EXPERIMENT 7.—Agar and gelatin plates were exposed to the ozone; some of the plates were streaked with *B. coli* and *B. pyocyaneus* both before and after exposure. The experiment was carried out under the same conditions as the preceding experiments and the exposure was for five hours. The machine was run at the highest speed and the concentration of ozone determined after two hours and after five hours. After two hours' running the concentration was found to be 3.6 parts per million and after five hours, 4.8 parts per million. All the plates exposed were directly in front of the exhaust and as close as possible to the machine. The following showed good growth:

Agar exposed and streaked with *B. coli* afterward.
Agar unexposed and streaked with *B. coli.*

Agar exposed and streaked with *B. pyocyaneus* afterward
Agar unexposed and streaked with *B. pyocyaneus.*
Agar streaked with *B. pyocyaneus* and then exposed.

---

[*] This investigation was carried on at the suggestion of, and under a grant from, THE JOURNAL of the American Medical Association.

[*] Tabular matter, certain details of investigation, etc., are here omitted. The article will appear in full in a pamphlet, a copy of which may be had by sending stamped, directed envelope to this office.

Gelatin exposed, then streaked with *B. pyocyaneus.*
Gelatin unexposed and streaked with *B. pyocyaneus.*
Gelatin streaked with *B. pyocyaneus* and then exposed.

One day later good growths developed in the following tubes:

Gelatin exposed, then streaked with *B. coli.*
Gelatin unexposed and streaked with *B. coli.*
Gelatin streaked with *B. coli* and then exposed.

EFFECTS OF OZONE ON AIR BACTERIA

In the following experiments the conditions were the same as in the preceding experiments. The dust in the experimenting-room was stirred up by the use of a rag; the room was then closed for fifteen minutes to allow the dust to become evenly mixed with the air. At the end of this period four sterile agar plates were exposed for a period of twenty-five minutes, at the end of which the plates were collected from the various points in the room where they were exposed and incubated for twenty-four hours at 37 C. (98.6 F.). At the end of the twenty-five-minute period the electric fan in the ozonator was allowed to run for one hour, after which four more agar plates were exposed in various places for the original period of twenty-five minutes. At the expiration of this period the plates were collected and incubated for twenty-four hours at 37 C. This experiment was carried out in the morning. The room was left alone until the same afternoon, at which time the dust was stirred up as in the morning and then left for fifteen minutes. Then the same experiment was carried out as in the morning with the exception of the running of the electric fan, in place of which the ozonator was allowed to run at Speed 2 as in the previous experiments. Twenty-four hours later the colonies on the plates were counted. The results were as follows:

Experiment 8.—Four plates were exposed for twenty-five minutes.

Exposure	Colonies
Before running of fan	38
After running of fan	56
Before running ozonator	64
After running ozonator	38

Experiment 9.—Four plates were exposed for twenty-five minutes.

Exposure	Colonies
Before running of fan	28
After running of fan	23
Before running ozonator	49
After running ozonator	18

Experiment 10.—This experiment was carried out in the same room and with the same machine as the preceding experiments. Five agar plates were exposed to the air at various points in the room for a period of thirty minutes before and after the running of the electric fan and the ozonator. The number of colonies before running the fan was fifty-eight; after running the fan, seventy-three.

Plates were now exposed at the same points and then the ozonator, instead of the electric fan, was allowed to run for an hour. The number of colonies before running the ozonator was sixty-one; after running the ozonator. sixty-seven.

Experiment 11.—This experiment was carried out as Experiment 10 with the exception that the dust was stirred up in the room thirty minutes before exposure of the plates before running the ozonator and the fan. The number of colonies before running the fan was seventy-one; after running the fan, fifty-seven. The number of colonies before running the ozonator was seventy-eight; after running the ozonator, thirty-four.

The results of these experiments show that:

1. No surely germicidal action on certain species of bacteria could be demonstrated by the usual disinfection tests with amounts of gaseous ozone ranging from 3 to 4.6 parts per million.

2. The alleged effect of ozone on the ordinary air bacteria, if it occurs at all, is slight and irregular even when amounts of ozone far beyond the limit of human physiologic tolerance are employed.[6]

[Review of early investigations omitted.]

The most recent contribution to the physiology of ozone is that of Hill and Flack.[7] These investigators failed to obtain any evidence that ozone in small concentrations stimulates the respiratory metabolism, but they confirm Bohr and Maar in finding that any considerable concentration (even less than 1 per million) of ozone diminishes the oxygen intake and the carbon dioxid output. This was established for mice, rats and man. Exposure of ten minutes to ozone in concentrations of 1 part to five millions may lower the rectal temperature of rats as much as 3 degrees.

Hill and Flack also observed the depression and coma following the initial restlessness on breathing strong concentrations of ozone (from 2 to 20 parts per million of air).

THE OZONE GENERATOR

The ozone in our experiments was produced by the "Ozonator" manufactured by the General Electric Company, the type for the direct current. The company states that this machine gives a flow of ozonized air of about 4,250 cubic feet per hour. The machine is made to deliver ozonized air in two different concentrations, designated as 1 and 2. The change from 1 to 2 is made by simply turning a key.

The method of Baumert as modified by Hill and Flack was used for determining the ozone concentration. Ten liters of ozonized air were drawn through a bottle containing 50 c.c. of 1 per cent. solution of potassium iodid acidified by 5 c.c. of 10 per cent. solution of sulphuric acid, 1 c.c. of 1 per cent. solution of boiled starch added, and titrated with the hyposulphite solution. The hyposulphite solution was made up to contain 0.222 gm. per liter, so that 1 c.c. of the solution represented 1 part of ozone per million parts of air when 10-liter air samples were used.

Tests of the air coming directly from the machine yielded the following results: Concentration 1, from 4 to 5 parts of ozone per million parts of air. Concentration 2, from 10 to 11 parts of ozone per million parts of air. After five weeks' more or less constant use each day the machine yielded a somewhat lower ozone concentration.

Tests for the oxids of nitrogen in the ozonized air were made after the machine had been in use five weeks, with negative results.

THE INFLUENCE OF STRONG CONCENTRATIONS OF OZONE ON MAMMALS

These results simply confirm the findings of previous observers. Ozone in any considerable concentration is an intense irritant to the respiratory tract and other mucous membranes, and causes illness and death from edema of the lungs.

THE RATE OF DECOMPOSITION OF OZONE BY THE MUCOUS MEMBRANES OF THE NOSE AND THE PHARYNX

In three dogs and two rabbits tracheotomy was performed under ether, a tracheal cannula inserted well below the larynx, the wound treated with cocain, and the animals allowed to recover from the ether anesthesia. In these animals the ozonized air entered the trachea directly, and no air entered the nose and larynx. When these animals were exposed to ozone in concentrations of 10 parts to one million parts of air, the irritation and edema of the trachea and the lungs developed much sooner than in the animals breathing through the nose—on the whole about four times faster. It thus takes only about thirty minutes' exposure to develop the degree of hyperemia and edema of the bronchi and the lungs produced by a two hours' exposure in the animal breathing through the nose. Evidently at least three-fourths of the ozone in the inspired air is decomposed by the mucous membrane of the upper end of the respiratory passages. The strength of ozone in the inspired air is therefore no measure of the concentration of ozone that comes in contact with the alveolar epithelium. This rapid destruction of the ozone by the mucous membrane of the upper end of the respiratory passages acts, of course, as a protecting mechanism for the lung tissue.

---

[6] After the work recorded in this paper was practically completed an article by Konrich appeared, Zur Verwendung der Ozone in der Lüftung, Ztschr. f. Hyg., 1913, lxxiii, 443. The results of this observer are essentially similar to our own.

[7] Hill and Flack: Proc. Roy. Soc., 1911, lxxxii, 404; Jour. Roy. Soc. Arts, 1912, lx, 344.

Our results on this point find corroboration, indirectly, in the observations of Hill and Flack that there is no demonstrable amount of ozone in the expired air when one is breathing an air-ozone mixture.

THE INFLUENCE OF OZONE IN THE INSPIRED AIR ON THE HEART AND THE BLOOD-PRESSURE IN THE DOG

As already pointed out, a stage of depression and drowsiness or coma due to breathing ozone in strong concentrations has been noted by many observers. Binz went so far as to assert that ozone was a sleep-producing gas. The depression or coma was very evident in our animals. And during this work with the animals one of us (A. J. C.) unavoidably breathed ozone in varying concentrations for short periods. If the ozone concentration was fairly strong, or if the weaker ozone concentrations were respired for longer periods, drowsiness and headache invariably followed.

It is quite evident that the ozone in the respired air does not reach the blood-stream. What, then, is the cause of the headache and the depression or drowsiness? These symptoms may be due to:

1. Depression of the tissue metabolism in consequence of the depression of the gaseous exchange in the lungs, as shown by the investigations of Bohr and Maar and of Hill and Flack.
2. Reflex effects on the central nervous system from the irritation of afferent nerve endings in the respiratory passages.
3. Cardiac and vasomotor changes due to *(a)* the stimulation of nerve endings in the respiratory tract, or *(b)* the altered metabolism of the tissues.

So far as we are aware the cardiac and vasomotor changes on exposure to ozone have not been extensively studied. Our method of procedure was as follows:

[Description of method omitted.]

When the animal breathes in the normal way through the nose, the ozonized air always causes a primary acceleration of the heart and an increase in the amplitude of the pulse. There is usually not very marked change in the carotid blood-pressure during this first phase. The changes in the heart activity have been observed *pari passu* with a lowered as well as with an increased blood-pressure. If the exposure to the ozone is continued for from thirty to sixty minutes, the strength of the heart-beat gradually fails and there is a corresponding gradual fall of the carotid blood-pressure. A typical tracking showing these changes at the beginning of an ozone period is given in Figure 1. The final weakening of the heart and lowering of the blood-pressure is illustrated in Figure 2.*

In one case we were fortunate in securing record of the heart-beat and the blood-pressure during what seems to be a period of Cheyne-Stokes respiration. This came on ten minutes after the cessation of a thirty-minute breathing (tracheal tube) of ozone in the concentration of 10 parts to one million parts of air. The somewhat labored and irregular respiration stopped abruptly, and we thought that the animal was about to die from respiratory failure, but we decided not to resort to artificial respiration so long as the heart was in fair condition. After a respiratory standstill for four and one-half minutes, five fairly strong respiratory movements were made spontaneously, and then followed a second standstill for two minutes, and again two respiratory movements followed by a third period of standstill lasting for one minute. After this third period the respiratory movements persisted with fair regularity. The blood-pressure record is reproduced in Figure 3.*

The slowing and weakening of the heart at the beginning of the first and longest period of respiratory standstill is in all probability due to vagi action (stimulation of the medullary centers by the increased carbon dioxid in the blood). The apparent recovery of the heart strength before the reappearance of the respiration is probably due to the initial stimulating action of increased carbon dioxid on the heart tissues directly, as shown by Henderson and by Starling. This condition of the heart persists despite the two brief periods of respiratory movements, because these were not sufficient to remove the excess of carbon dioxid, especially as activity of the lung tissue was greatly depressed by the ozone. The rapid and temporary rise of the carotid blood-pressure simultaneously with the respiratory period must be due to some association between the respiratory and the vasoconstrictor centers in the medulla.

When these striking changes in the heart and the respiration appeared, the dog was already in a state of marked depression or coma. There can be no question that the feeble heart-beat and low blood-pressure noted after prolonged exposure to strong ozone concentrations are factors in the depression or coma following the ozone breathing; but these changes are also accompanied by irritation, depression and edema of the respiratory tract. The drowsiness and headache produced by ozone in man certainly appear long before there is any marked edema of the respiratory tract, weakening of the heart, or persistent lowering of the blood-pressure. The cardiac and vasomotor changes that are seen in dogs at the beginning of the ozone exposure do not seem sufficient to cause drowsiness or headache. In order to settle this point more definitely the following experiments were made on man.

THE INFLUENCE OF BREATHING OZONE ON THE HEART AND THE VASOMOTOR MECHANISM IN MAN

Three men (A. J. C., F. H. M., W. A. S.) served as subjects in these tests. The blood-pressures were recorded by the Erlanger sphygmomanometer, the cuff being adjusted to the left arm. The subject sat a few inches away from and facing the ozonator, so that the respired air contained the full concentration of ozone as it came from the machine (5 parts and 10 parts per million, respectively). The results were uniform and practically without exception. The respiration of ozone caused an increase in the amplitude of the heart-beat, without any appreciable or constant change in the rate of the beats or in the blood-pressure. It is to be noted, however, that the exposure to the ozone was of brief duration, that is, only long enough to complete a test. Typical records obtained by the sphygmomanometer under these conditions are reproduced in Figure 4.

---

* Figures omitted here are included in reprints.

The exposure to ozone during these tests was sufficient to cause drowsiness and headache. One of the subjects actually fell asleep during one test. This happened to be a test with the plethysmograph, but there was no vasodilatation of the arm similar to that of normal sleep. Possibly the sleep was too brief and too light for this reaction to appear. It does not seem to us that the cardiac and vasomotor changes revealed by these tests are sufficiently great to account for the drowsiness and the headache.

The ozone headache may come on during or shortly after a brief exposure to ozone in greater dilutions; in some cases it comes on two or three hours after the exposure. If the ozone exposure has been rather marked the headache may persist for from two to six hours. According to our experience, it is always a frontal headache, similar to that in the case of "head-cold." We believe that this headache is due to irritation and consequent hyperemia of the frontal sinuses by the ozone. This view is supported by the fact that such hyperemia of the sinuses is actually present in dogs after exposure to ozone.

In this connection we may note that the breathing of ozone in concentrations up to 10 parts per million for short periods not exceeding a total of fifteen minutes produces "sore throat" that persists for two or three days. The "sore throat" is occasionally accompanied by some pain in the chest. These conditions are evidently due to the corrosion of the mucous membrane by the ozone.

One of the subjects (W. A. S.) had "sore throat" ("cold") at the beginning of these experiments. We had here an opportunity to see whether or not the inhalation of ozone in the greatest concentration that may be used with safety for a short period will check the bacterial invasion of the throat either by directly killing the bacteria or by producing hyperemia through the irritation, as suggested by Hill and Flack. The daily exposure to the ozone not only did not improve, but actually aggravated the sore throat. It is not improbable that the impairment of the cells of the mucous membrane by the corrosive action of ozone renders the cells less resistant to bacterial invasion.

CAUSE OF THE DROWSINESS, DEPRESSION AND COMA FOLLOWING EXPOSURE TO OZONE

We have seen that the cardiac and vasomotor changes are probably not important factors. There remains then to consider the part played by direct depression of the nervous system from stimulation of the nerve endings in the respiratory tract, by the absorption of toxic substances from the cells of the respiratory tract injured by the ozone, or by the lowered metabolism of the tissues following the diminution of the gaseous exchange in the lungs.

It would seem that, if the afferent impulses play an important part in the depression and coma, these effects ought to be influenced by tracheotomy and section of both vagi. When the animal breathes through a tube inserted well below the larynx, the irritation of the upper end of the respiratory tract by the ozone is eliminated. Section of both vagi cuts off (at least in the main) the nervous impulses from the lungs and the bronchi.

A number of tests were made on dogs and rabbits thus prepared. The changes in the respiratory movements following double vagotomy, especially in dogs, are disturbing factors. Our results showed that animals with both vagi cut succumb more quickly from ozone than the animals with the vagi intact, but the depression and coma are not apparent until a degree of lung injury is reached from which the animals do not recover. When the vagi are intact the animals may recover completely from exposures to ozone sufficient to cause marked depression.

It would therefore seem that the afferent nervous impulses due to the irritation of the respiratory tract by the ozone contributes to the ozone depression and coma, but that the changes in the metabolism, and possibly in the composition of the blood, are by themselves capable of causing depression, especially after prolonged ozone exposure.

THE INFLUENCE OF WEAK CONCENTRATIONS OF OZONE BREATHED FOR LONG PERIODS

The physiologic tests with ozone so far dealt with involve an ozone concentration that might be employed in experimental therapeutics, but which is out of the question for the purposes of ventilation. For ventilation purposes the ozone must not reach a concentration that leads to irritation and obvious injury, or too intense odor. This concentration is considerably below 1 part of ozone per million parts of air. Most people can probably tolerate a strength of the ozone odor represented by an ozone concentration ranging from 1 in twenty millions to 1 in five millions, although to some persons even the faintest odor of ozone is disagreeable. What is the physiologic action of ozone at such low concentration? On this point we have the assertions of parties financially interested, and the assertions of enthusiasts not hampered by a critical judgment, but practically no facts. Thus we are told that a few months' use of ozone in the ventilation system increased the chest expansion of office workers by several inches; that the favorable influence of mountain climates is due to the trace of ozone in the mountain air, etc.

Bohr and Maar and Hill and Flack have shown that ozone depresses the gaseous exchange in the lungs before there is any demonstrable injury to the lung tissues, or in concentration too weak to produce inflammation and edema. This would constitute a decidedly injurious influence of ozone. But it is obvious that the ozone concentrations employed by these observers were greater than that permissible in practical ventilation.

Concentrations of ozone of 1 part per million parts of air are certainly injurious, but it does not follow that the weaker concentrations of ozone are proportionally injurious. It is furthermore certain that the animal organism is capable of compensating for or repairing very slight injurious actions of ozone as well as of other toxic substances. It will therefore be very difficult to obtain reliable evidence as to any favorable or unfavorable physiologic action of such ozone concentrations as are practicable in ordinary ventilation. Nevertheless the following test was carried out:

Four cats, four rabbits, six guinea-pigs, and twelve rats were placed in comfortable cages in a room of twenty-six cubic meters' capacity. The ventilation arrangements of this room were such that the air of the room could be renewed at a rate varying from thirty minutes to about twelve hours. The room was provided with double doors and double windows. The inside door was provided with a large glass panel, so that it was possible to observe the animals without entering the room. The ozonator was placed in the room in such a position that none of the animals were in the direct line of the ozonized air current. The samples of air from the room for the ozone estimations were secured by glass-tubing connections through the wall. The glass tubing was placed so that air samples could be taken near the floor near the ceiling, and midway between the floor and the ceiling.

When the number of animals mentioned were in the room, and the rate of exchange of the air in the room was adjusted to about two hours, running the ozonator at the highest concentration capacity for five minutes brought the ozone concentration in the room up to about 1 part per million parts of air. In from twenty-five to thirty minutes after stopping the ozone generator, the ozone in the room had been removed or decomposed to such an extent that it was no longer irritating to the eyes and nose; but it could still be detected by its odor. At this point the ozonator was again turned on for five minutes. This process was kept up for about nine hours each day (from 8 a. m. to 5 p. m.) for a period of two weeks.

The points taken into consideration were, body-weight, appetite and general condition. The animals were kept in the cages in this room from February 24 to March 10, that is for two weeks before the ozone test was started, in order to secure controls. We aimed to select only healthy and vigorous animals, but one of the rats proved to have advanced tuberculosis of the right lung. This rat developed marked irregularities of the respiration at the end of the first week of the ozone exposure, and died on the tenth day. Post-mortem examination showed pneumonia ("red hepatization") of the lung not affected by tuberculosis. It is not improbable that this pneumonia was caused by the ozone, but no conclusion can be based on a single case.

One of the rabbits proved to be pregnant, and gave birth to two young ones, March 21, that is, on the eleventh day of the ozone exposure. One of the young was still-born and weighed only 60 gm., and the mother neglected the other one. We are of the opinion that the birth was a premature one by at least a week. It was noted that the new-born rabbit was more strongly affected (irregularity of respiration) by the ozone than the adult rabbits.

Each animal was weighed once a week. The general summary is presented in Table 7 [omitted]. All the animal groups showed some increased body-weight, but the increase during the control period is practically the same as during the ozone period. Slight differences are of no significance. Hence, as regards appetite and body-weight the results of the test are negative, the ozone appearing to have neither a favorable nor an unfavorable influence. This applies also to the general conditions of the animals. The cats did not seem disturbed even when the ozone concentration approached one to a million, but this concentration caused some restlessness in the rabbits, guinea-pigs and rats. In all other respects the animals appeared to be normal.

We desire to state, however, that this test does not warrant the conclusion that the ozone concentrations that may be used in practical ventilation is harmless to man. Two weeks is a short time in the life of a man. If ozone in ventilation should come into general use, it would mean in the case of office- and shop-workers exposure to ozone from six to ten hours a day, six days of the week, from nine to twelve months of the year for from twenty to fifty years. And even if this prolonged exposure to ozone should prove harmless to the robust person, what about the unfortunate person whose lungs have only slight power of resistance?

[Review omitted.]

EXPERIMENTAL PROCEDURE

Our tests were conducted in the room used for the prolonged test on the animal groups. The room was of convenient size (26 cubic meters) and permitted adequate control of the rate of renewal of the air.

The following odorous substances were used: ammonia vapor, hydrogen sulphid, oil of cloves, asafetida, human feces, stale (or decomposed) urine, meat in advanced decomposition, musk, the odor of rose and the odor of lilac.

We aimed to secure comparable concentrations of the odors in the room by evaporating fixed quantities of the odorous material, and by exposing equal quantities of the odorous substances equal lengths of time. The rate of disappearance of the odors from the room under uniform conditions of the room ventilation was noted and this constituted our control. The ozone tests were made with reference to these three points:

1. The concentration of the ozone required to mask the odors.
2. The possible destruction of the odorous substances by ozone in strong concentrations.
3. The possible destruction of the odorous substances by ozone in concentrations just sufficient to mask the odors.

RESULTS

Our results agree with those of Erlandsen and Schwarz, Hill and Flack, and Konrich as regards the power of ozone in strong concentrations to mask all the before-mentioned odors. With the exception of ammonia and the oil of cloves all of these odors are completely masked by ozone below a concentration of one to a million. The masking of ammonia and clove oil requires a much stronger concentration of the ozone, a concentration sufficient to cause marked irritation and headache even on short exposure.

When the ozonator was allowed to run just long enough to cause complete ozone masking of the odors there was no appreciable destruction of the odorous substances by the ozone. The ozone odor disappeared before the specific odor under investigation, and the rate of disappearance of the latter was approximately the same as in the control tests.

Strong concentrations of ozone (from 2 to 5 parts to the million) hastened somewhat the rate of disappearance of the odors of feces, stale urine and decomposing meat. Strong concentrations of ozone are therefore capable of causing some destruction of these odorous substances. In the case of the other odors there was no evidence of actual destruction by ozone in concentrations up to 5 parts per million. Stronger ozone was not tried.

The inability of ozone to oxidize (to any appreciable extent) ammonia vapor and oil of cloves is very striking. These odors may be masked three or four times in succession during a single test, and the ozone disappear sufficiently for the specific odor to be smelled.

The mechanism of this masking action of ozone does not concern us here. Two factors appear to be involved. First, the preponderance of the powerful ozone odor in consciousness, and secondly, a fatigue of the olfactory end-organs by the ozone. Strong concentrations of ozone rapidly fatigue or anesthetize the olfactory epithelium. From 5 to 10 parts of ozone per million parts of air can be smelled for less than a minute despite its continued presence in the nose. After the first minute one is aware of the ozone irritation but not the ozone odor.

The assertion is frequently made by parties financially interested in the practical uses of ozone that "ozone destroys smoke." "Smoke" is composed of particles of carbon or soot plus various gases, such as carbon monoxid, sulphurous acid, etc., depending on the material burnt and the availability of oxygen during the process of combustion. But as ordinarily understood the word "smoke" means essentially particles of carbon or soot. And when the assertion is made that "ozone destroys smoke," the average reader takes that to mean that ozone destroys soot. Such an assertion is equivalent to a deliberate deception, because there is no evidence that ozone even in the greatest possible concentration can oxidize carbon particles suspended in the air in the form of smoke or soot. The inability of ozone to "destroy" carbon particles in the form of smoke or soot can readily be demonstrated by the following experiment: A piece of glazed paper is coated uniformly with a thin film of lamp-black or soot, the paper cut in halves, one part fixed in shellac for control, and the other part exposed to ozone. We have exposed such smoked paper 2 inches in front of the generator running at the highest concentration (10 parts per million) for ten consecutive hours without the slightest reduction of the amount of soot on the paper. If this is true in the case of ozone in very great concentration it must be true of ozone in concentrations that are permissible in actual ventilation.

SUMMARY AND CONCLUSIONS

In view of the evidence already in existence, the hygienic value of ozone in room ventilation would be hardly worth considering were it not for the persistent and sometimes extravagant claims made by the manufacturers and promoters of ozone generators.

So far as the destruction of bacteria is concerned, these claims have little or no foundation. Some bacteria are undoubtedly killed by ozone, especially if they are in a moist condition and are in contact for several hours with a current of ozone coming direct from the generator. In practice, however, the fact is of slight importance. Human beings are injuriously affected by amounts of ozone far less than are necessary to produce even this slight bactericidal effect, and there is no evidence for supposing that a quantity of ozone that can be tolerated by man has the least germicidal action. If disinfection of a closed room without inmates is desired, this can be much more effectively carried out by the use of formaldehyd or some other familiar gaseous disinfectant than by ozone. Ozone has no place in practical room disinfection.

Ozone is not an actual "deodorizer" in concentrations that can obtain in practical ventilation. In very great concentrations ozone seems capable of oxidizing some odorous substances so that the odors are diminished or changed, but the change may be in the direction of increasing the disagreeableness of the odor. In very great concentrations ozone "masks" most odors and possibly by fatigue or by its own intensive odo anesthesia of the olfactory epithelium. Certain odors are masked by ozone even in weak concentrations. Is such masking of odors desirable and generally advantageous? We think not. It is probable that the injury to the respiratory tract by ozone in sufficient concentration to act as an effective mask is of greater moment than the deleterious action of most odors. Except in special industrial processes, the unpleasant odor of the inspired air in shops, offices or living-rooms is usually a sign that the air needs to be renewed or changed as regards not only the percentage of odorous substances, but also, and of greater importance, the percentage of moisture and the degree of temperature. Why should we put out of commission the sense organ which aids us in determining whether or not the air is fit to breathe? It seems to us that this is wrong in principle, and that ozone is being used and will be used as a crutch to bolster up poor ventilating systems. Ozone does not make "pure air" any more than strong spices make pure food.

In concentrations that appreciably affect man and animals, ozone appears to have uniformly an injurious action. This injurious action is primarily on the respiratory passages—irritation of the sensory nerve endings, and irritation, corrosion and depression of the epithelial cells. The depression of the alveolar epithelium leads to changes in the gaseous exchange in the lungs, and secondarily to changes in the blood. The ozone headache is due to irritation, corrosion and consequent hyperemia of the frontal sinuses. The depression and drowsiness which are produced by ozone are due to the intense irritation of sensory nerve endings in the respiratory tract as well as to the secondary effects of the change in the activity of the alveolar epithelium.

Hill and Flack[7] point out that ozone gives a certain "tang" to the air, and thus relieves the impurity of the air (temperature and moisture) which is apt to obtain in the air in offices and assembly-rooms. This tang is a combined effect of ozone odor and the ozone irritation of the sensory nerves in the respiratory tract. We have seen that this acts (reflexly) on the vascular mechanism and it may temporarily "whip up" a fagged brain. But is this ozone tang any more beneficial or any more physiolgic than a whiff of smelling-salts or a puff of the cigarette? We recognize that a certain amount of variation in the rate of movement and in the temperature of the air about us aids in maintaining the tonus of the brain, but our ventilation engineers must reproduce the variability of outdoors by actual variations in the air and in the rate of movement of the air in the ventilating systems, and not by adding a poisonous gas to the air. Nor can we accept the suggestion of Hill and Flack that small amounts of ozone may be of therapeutic value in certain diseases of the respiratory tract by reason of the hyperemia following the ozone irritation. The ozone irritation leads to intense hyperemia of the respiratory tract, but this hyperemia is obviously correlated with repair of the injury to the epithelial cells wrought by the ozone. The cells injured by ozone are probably more readily invaded by bacteria, and have less than normal power of growth and healing despite the hyperemia. And all bacteria so far studied are much more resistant to ozone than are the cells of the respiratory tract of man and experimental animals. The physiology of ozone points to the conclusion that the use of this poisonous gas as a therapeutic agent is either valueless or injurious.

THE ALLEGED PURIFICATION OF AIR BY THE OZONE MACHINE *

W. A. SAWYER, M.D.
Director of the Hygienic Laboratory of the California State Board of Health

HELEN L. BECKWITH, B.L.
AND
ESTHER M. SKOLFIELD, A.B.
Assistant Bacteriologist in the Hygienic Laboratory of the California State Board of Health

BERKELEY, CAL.

The experiments of a number of careful investigators have discredited the claims made for ozone as a purifier of air. Largely on the basis of claims already disproved, several manufacturers are so successful in introducing ozone machines into public buildings that this purposeful adulteration of the air with ozone and its accompanying impurities threatens to become a public health problem.

Ohlmüller[1] demonstrated that ozone in considerable strength was incapable of killing dry bacteria within the time-limits of his tests. Erlandsen and Schwarz[2] showed the falsity of the claim that the presence of free ozone means the absence of organic impurity in the air. They demonstrated, through careful analyses, that ammonia and hydrogen sulphid were not diminished in amount by the presence of ozone. They showed also that the deodorizing property of ozone consisted of the masking of one odor with another. In their experiments with a number of odorous substances, the masked odors again became evident when the odor of the ozone had diminished. Filipow[3] demonstrated that strong concentrations of ozone in respired air caused a marked irritation of the mucous membranes. Hill and Flack[4] showed that a concentration of ozone as small as one part per million was irritating to the respiratory tract and that exposure for two hours to fifteen or twenty parts per million was not without risk to life. They demonstrated that the respiratory metabolism was reduced by the inhalation of ozone.

In September, 1912, the fifteenth annual convention of the League of California Municipalities and the fourth annual conference of state, county, and municipal health officials were held on the campus of the University of California. In connection with these meetings there was a "Public Welfare Exposition" consisting chiefly of the exhibits of manufacturers. An attempt was made by the agent for an ozone machine (designated in this paper as "Machine A") to display his apparatus and literature in that part of the exhibit which was devoted chiefly to foods and was under the supervision of M. E. Jaffa, director of the State Food and Drug Laboratory. Jaffa refused to permit the ozone machine to be exhibited, on the ground that the advertising circulars made claims which could not be true. The decision was protested and was referred to the director of the Hygienic Laboratory of the California State Board of Health, who sustained it, laying special stress on the false claims of bactericidal efficiency for ozone. This action was repeatedly protested, and requests were made that the machine be given a laboratory test. As a result the few simple experiments reported in this paper were performed with the ozone machines of two well-known companies. It was proposed to show the relative killing power for animals and bacteria. No attempt was made to measure the quantities of ozone, oxids of nitrogen, or other gases, which may have been included in the composition of the "ozone" produced by the machines.

The machines examined were loaned for our tests by the local agents of the manufacturers, and we wish to express our appreciation of the uniform courtesy which was extended to us.

Machine A was intended for use in a large room containing about fifteen people. Unlike Machine B, it had no attached apparatus for agitating the air. Circulars put out by the manufacturers state that ozone is a "necessity" for the destruction of infectious germs and bacterial life, for the sterilization of air in operating-rooms, for the purification of the air in homes of persons suffering from contagious diseases, and for giving to offices and homes the invigorating air of the country, seashore and mountains.

Machine B also was intended for purifying the air of a large room. The machine included a motor and fan for blowing air through the apparatus and out into the room. A well-illustrated advertising pamphlet from the manufacturers includes the statement that ozone cannot exist except momentarily in air containing organic matter, and that therefore the presence of ozone is an indication that the air is sterile and devoid of organic matter. In a quoted article the pamphlet asserts that ozone is unique as a germicide by reason of the fact that it has no deleterious effect on the higher forms of animal life, owing to the low percentage of carbon contained in their structure.

For our experiments a tight wooden cabinet with a capacity of 1 cubic meter was constructed. The door of the cabinet had a glass window which permitted a view of the interior. The ozone machine under test stood in the middle of the cabinet. The humidity was indicated by wet- and dry-bulb thermometers. In some of the experiments the humidity of the air was increased by pouring hot water through a tube into a dish standing in the cabinet. The guinea-pigs which were subjected to the "ozone" were placed in a small wire cage where they could be seen through the glass door. The bacterial cultures used were grown for a day on meat-extract broth. Sterile glass rods were dipped into the cultures and the broth was dried on them in an almost invisible film. These rods were fixed in large corks and were inserted into the cabinet through holes drilled near the top. After exposure to the "ozone" the rods were withdrawn and their ends were dipped into tubes of broth. After forty-eight hours of incubation, the clouded cultures were tested to find whether or not the growth was due to the organism originally placed on the rod. The streptococcus and staphylococcus cultures in all instances showed organisms of the characteristic morphology. The typhoid cultures were tested by agglutination with antityphoid serum. The cultures of *Bacillus subtilis* were sufficiently identified by the appearance of the scum growing on the surface of the broth. In the tables the plus sign denotes that the organism exposed in the test grew in the subculture. The minus sign signifies that the subculture was sterile.

The experiments with Machine A were made in several separate tests, and the results are brought together in Table 1. The cultures which were dried on threads were placed in open Petri dishes on the bottom of the cabinet. The control cultures were exposed to the air in a locker in the laboratory.

Guinea-pig 1 seemed sluggish and was breathing rapidly at the end of an hour. In two hours and forty minutes it was dead. Necropsy showed marked edema of the lungs.

The tests with Machine B were carried on both with and without added moisture. The various cultures and the guinea-pig were put into the cabinet and the machine was started at the time of beginning each experiment. The door was not opened until the test was finished.

Guinea-pig 2 showed labored breathing twenty minutes after the machine was started. Twenty-five minutes after beginning, it began rubbing its nose with its fore feet; after forty-five minutes it was drowsy; at the end of an hour its eyes were watery and almost closed, and its nose was wet. After an hour and a half its breathing was irregular and spasmodic. A little later there were convulsive movements. After an hour and forty minutes it was struggling for air and in an hour and fifty-five minutes it died. Necropsy showed marked edema of the lungs. They did not collapse and were filled with foamy fluid.

Guinea-pig 2, 314 gm.		Sick			Dead						

As all the guinea-pigs showed similar symptoms during life and marked edema of the lungs on necropsy, details will be omitted in the subsequent experiments.

Guinea-pig 3 died four hours and thirty-three minutes after the machine was started.

Guinea-pig 4 died one hour and thirty-five minutes after the machine was started.

In a fourth test of Machine B the conditions were the same as those shown in Table 4, except that the machine was run at strength 1, instead of at the highest strength. The experiment was begun at 9:40 a. m., June 2. No moisture was added t[illegible]ir, and the average of the humidity estimations was 62.9 per cent., which is lower than the average (73 per cent.) of the readings in Table 4. The average temperature was 20.3 C. (68.5 F.), which is two degrees lower than the average during the previous test. A table of the results is not presented as the four kinds of bacteria withstood the entire twelve hours of exposure. The guinea-pig (weight, 325 gm.) died in less than one-eighth of that length of time. It showed disturbance of respiration almost immediately after the machine started and died one hour and twenty-five minutes later.

The agents for Machine B sent us another machine (C), which was similar to the other, although of lower capacity. When it was run at the greater of its two possible strengths, without the addition of moisture to the air of the cabinet, the results were similar to those presented in Table 3 for Machine B. This showed that the results obtained were not due to individual imperfections in one machine.

Comparison of the tables shows that the addition of moisture to the air in the cabinet increased the slight bactericidal effect of the "ozone." In every test in which the guinea-pig and the bacteria were in the cabinet together, the bacteria outlived the guinea-pig.

Additional tests of the bactericidal power of the "ozone" were performed in two bedrooms in a dwelling-house. A room containing 730 cubic feet of air-space was prepared by packing the spaces about the windows and doors with cotton. A similar room was used for exposing control cultures to the drying influence of air. In testing the ozone machines in the room the same varieties of bacteria were exposed as in the tests with the corresponding machines in the cabinet, and the cultures were dried on glass rods in the same manner. Machine A was run at its maximum strength for sixteen hours in the closed room. Subcultures were made when the room was opened, and the organisms grew in all instances. Machine B was run at its maximum strength (No. 3) for sixteen hours in the same room. The cultures all survived the test, but a guinea-pig (weight, 213 gm.), which had been put in a cage in the room, was found dead when the door was opened. Necropsy showed edema of the lungs. The humidity of the air in the room at the beginning of the test was 61 per cent. of saturation and the temperature was 22 C. (71.6 F.). When the room was opened in the morning a faint haze was visible in the air.

During these tests certain physiologic effects of the "ozone" were noticed by the experimenters after they had been working around the machines. The immediate effect of inhaling the diluted gas was a feeling of dryness or tickling in the nasopharynx, and sometimes the irritation was felt in the chest. If the exposure was prolonged, watering of the eyes, and occasionally a slight headache, resulted. The smell of the "ozone" and its irritation was much more noticeable to persons who came suddenly under its influence than to those who were continuously exposed. This shows the disadvantage of entrusting the regulation of an ozone machine to persons who are constantly breathing its products.

CONCLUSIONS

1. The gaseous products of the two well-known ozone machines examined are irritating to the respiratory tract and, in considerable concentration, they will produce edema of the lungs and death in guinea-pigs.

2. A concentration of the gaseous products sufficiently high to kill typhoid bacilli, staphylococci and streptococci, dried on glass rods, in the course of several hours, will kill guinea-pigs in a shorter time. Therefore these products have no value as bactericides in breathable air.

3. Because the products of the ozone machines are irritating to the mucous membranes and are probably injurious in other ways, the machines should not be allowed in schools, offices or other places in which people remain for considerable periods of time.

4. The ozone machines produce gases which mask disagreeable odors of moderate strength. In this way the machines can conceal faults in ventilation while not correcting them. Because the ozone machine covers unhygienic conditions in the air and at the same time produces new injurious substances, it cannot properly be classed as a hygienic device.

CAUSES, TYPES AND TREATMENT OF DIARRHEA IN ADULT LIFE[*]

RICHARD C. CABOT, M.D.
BOSTON
AND
HAVEN EMERSON, M.D.
NEW YORK

We have undertaken a fresh study of this ancient problem, beginning with the necropsy records of Bellevue Hospital in New York and the Massachusetts General Hospital in Boston. In each of these institutions we examined three thousand necropsy records, searching for lesions ordinarily supposed to produce diarrhea. We then traced the cases showing these lesions back to the clinical records, trying to ascertain first whether the lesions actually produced diarrhea, and if so, in what proportion of cases; secondly, whether any special type of symptoms or of discharges was associated with any special lesion of the intestine, the endeavor being to mark out clinical types so far as this was possible. Finally, we reviewed the results of treatment both in necropsy cases and in a considerable series of cases which did not come to necropsy, and endeavored to estimate the value of the different methods used.

For various reasons we have excluded from this study certain diseases often associated with diarrhea. We have taken no account of the cases of typhoid fever, partly because the relation of this disease to diarrhea has already been thoroughly studied in large groups of cases, and, secondly, because we were anxious to get some idea of the relative frequency of the different cases with this symptom, and we are well aware that the number of persons sick with typhoid in these two hospitals was not a fair sample of the number of cases of this disease existing in the community outside, since cases of typhoid are quite abnormally collected from large areas in hospitals such as those in which we have pursued our studies. The parasitic diarrheas have also been excluded because of the small number of these cases available in Boston or New York. We have made no effort to study the cases of mercurial or arsenical poisoning or cases of dysentery due to organisms of the Shiga type, or other organisms closely allied to it. We have also excluded all cases occurring in persons under 16 years of age. Leaving out the types just mentioned, we have studied 640 cases of the varieties ranged in Table 1.

TABLE 1.—RELATIVE FREQUENCY OF DISEASES CAUSING DIARRHEA IN ADULTS—MASSACHUSETTS GENERAL HOSPITAL, 1905-1912

Acute enteritis and unknown (acute) causes—clinical cases.		244

DIFFICULTY OF DISTINGUISHING ACUTE FROM CHRONIC ENTERITIS AND COLITIS

It would have been desirable to distinguish clearly the acute from the chronic cases, but this we found unexpectedly difficult. The intestine is like the kidney in that a long-standing disease may show clinical symptoms only now and then, presenting itself suddenly under the guise of an acute disease.

---

[*] Because of lack of space, this article is abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints.

[*] Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-fourth Annual Session, held at Minneapolis, June, 1913.

After making these exclusions and explanations we turn to the first portion of our study.

CAUSES OF DIARRHEA

"Indiscretions in diet" have long been blamed for a large proportion of the brief diarrhea occurring in adults as well as in children. There is reason to doubt that these indiscretions are in a certain number of cases responsible, but a careful analysis of the records shows that many patients suffering from precisely the same symptoms as those supposedly due to indiscretions of diet have in fact committed no such indiscretions and eaten nothing unusual.

Among a group of eighty-nine patients suffering from acute benign diarrhea, presenting in the stools no evidence of bowel ulceration and recovering within from ten to fourteen days, forty-one patients ascribed the trouble to some supposed indiscretion in diet or to some food believed to have been poisonous, while forty-eight patients, exhibiting precisely the same symptoms, signs and course remembered no dietetic cause for their trouble and, indeed, no obvious cause of any kind.

"Ptomain poisoning" is one of the commonest, one of the most popular and fashionable diagnoses of the day among a certain class of practitioners. Yet this diagnosis will seldom stand criticism. Many of the cases to which this name is given turn out to be appendicitis, gall-stones, intestinal obstruction, pancreatitis, a gastric crisis in tabes, lead-poisoning and other diseases having nothing to do with ptomains.

We have merged in a single group a large number of cases variously designated on the clinical records because there seemed to be no good reason for the employment of the different terms such as dysentery, gastro-enteritis, enteritis, enterocolitis, colitis, etc. To the same group of cases, now one, now another of these terms is applied without any clear reason, according to the taste and fancy of the individual physician.

In a small group of cases, only seven, in the Massachusetts General Hospital series during a period covering the years from 1895 to date, there has seemed to be a genuine intolerance of the intestine for one or another foodstuff, chiefly fat. Intolerance for a protein or a carbohydrate was very rarely identified, but in the small group of cases previously referred to an excuse of fat was present in the stools on ordinary diet, and when a diet free from fat was given, the diarrhea ceased. In none of these cases was there any definite evidence of pancreatic disease or of any other organic cause for the anomaly, and no cases of diarrhea definitely to be referred to pancreatic disease were studied by us.

Passive congestion of the intestine is not a cause of diarrhea. This lesion was present in a large number of the cases of our series in which necropsy was performed, but was seldom associated with diarrhea.

Tuberculosis of the intestine is a favorite diagnosis among general practitioners confronted by intractable and chronic cases of diarrhea. In my experience such a diagnosis is almost never warranted, for it is likely to be made in patients showing no pulmonary lesions of tuberculosis and despite the well-known fact that tuberculous enteritis almost never occurs except as a complication of phthisis. A striking result of our studies was this: Even when there is a demonstrable tuberculosis of the intestine (complicating pulmonary disease) diarrhea occurs in only one case out of three. Thus in only ten out of thirty-one cases of tuberculous enterocolitis which came to necropsy at the Massachusetts General Hospital (32 per cent.) and in only twenty-nine out of one hundred similar cases studied post mortem at the Bellevue Hospital (29 per cent.) was diarrhea present. The two series of cases here support each other in a very striking way (Table 2).

Even when diarrhea occurs in patients suffering from distinct tuberculosis of the lungs, one is by no means certain that the flux is due to intestinal tuberculosis, for diarrhea is nearly half as common in cases of pulmonary tuberculosis without intestinal lesions as in cases with these lesions. Thus in 106 cases of pulmonary tuberculosis studied post mortem at the two hospitals referred to, fifteen, or 14 per cent., had diarrhea, although the intestines showed no lesions whatever. All this emphasizes the fact further to be insisted on that even when intestinal ulcerations are present in a case of diarrhea we are by no means certain that the ulcerations cause the diarrhea.

Cancer of the intestine was studied in 159 patients, post mortem or after operation, at the Massachusetts General Hospital, and in eighteen patients post mortem at the Bellevue Hospital. The percentage of diarrheas in these cases, taken as a whole, is almost identical with that found in tuberculous enteritis. Thus fifty-two, or 32 per cent., of the Massachusetts General Hospital cases showed a diarrhea either steadily or intermittently, while 22 per cent. of the Bellevue cases showed the same symptom. Contrary to the accepted idea on this subject, we did not find that diarrhea was any commoner in cases involving the lower part of the intestine than in those involving the upper part. Thus in forty-three cases of cancer of the rectum, diarrhea was present in 37 per cent., while in sixty-seven cases involving the hepatic flexure, the ascending colon or the cecum, diarrhea was present in 41 per cent. In thirty-two cases involving the intermediate portion of the colon including the transverse colon, the splenic flexure, and the descending colon (above the sigmoid), diarrhea was present in only 18 per cent.

In chronic renal disease, diarrheas of a supposedly compensatory type are often said to occur. Our studies did not tend to confirm this supposition, for in seventy-two cases of chronic nephritis diarrhea was present only eleven times either in the history previous to hospital treatment or during that treatment.

Intussusception has for many years been associated in text-books with a bloody diarrhea and been supposed to differ thereby from other types of intestinal obstruction.

TABLE 2.—RELATIVE FREQUENCY OF CERTAIN FATAL DISEASES ASSOCIATED WITH DIARRHEA (SIX THOUSAND NECROPSIES)

Disease	Bellevue Hospital 3,000 Necropsies		Mass. General Hospital 3,000 Necropsies		Per Cent. Having Diarrhea	
	Total Cases	No. of Cases of Diarrhea	Total Cases	No. of Cases of Diarrhea	Bellevue	Mass. Gen'l
Acute and chronic enteritis (unknown cause)	111*	45	71	32	40	45
Cancer of colon	18	4	64	20	22	32
Tuberculosis of intestine	100	29	31	10	29	32
Tuberculosis of the lungs; intestine not diseased	71	11	35	4	15	11

* Seventy classified as acute post mortem; twenty-five of these had diarrhea. Forty-one classified as chronic post mortem; twenty of these had diarrhea.

This idea was borne out only to a limited extent in the cases studied in the present series, for only three out of ten showed any diarrhea at all.

We have had no opportunity to advance our knowledge on the subject of so-called morning diarrheas, the association of which with achylia gastrica has recently been referred to.

Closely associated with these, according to our belief, is the type known as nervous diarrhea or simple hyperperistalsis. Presumably there is some connection here between the hyperperistalsis and low blood-pressure in the peripheral blood-vessels with vasodilatation in the splanchnic area. The feeble rapid heart and the tendency to faintness in such cases goes to strengthen this supposition.

An important group of cases, not very numerous, fortunately for us, but very obstinate and mysterious, are those associated with intestinal ulceration of unknown cause. Many of these cases are demonstrably nonamebic and not due to infection by any known type of micro-organism. Some of them bear the marks of infectious disease—fever, leukocytosis and albuminuria. In others there is no such evidence. The diagnosis is made from the condition of the stools (see hereafter) or by proctoscopy. Sixty cases of ulcerative colitis of this kind were studied at the Massachusetts General Hospital, beginning with the necropsy record and following the case back into the clinical history. One hundred and eleven similar cases were studied at Bellevue Hospital. In 55 per cent. of the Massachusetts General Hospital cases and 60 per cent. of the Bellevue cases diarrhea was absent, and the diagnosis of intestinal ulceration or ulcerative colitis was often quite unsuspected before necropsy. Even when the colon is deeply and universally ulcerated, "hanging in rags" as one of my colleagues expressed it, the bowels may be constipated throughout the disease. Although there is nothing new about this statement, we desire to emphasize it afresh, since there is so strong a tendency to use the words diarrhea and enteritis as synonyms.

In cases of enteritis without diarrhea the diagnosis is, so far as we can see, impossible, unless something suggests proctoscopy. There may be no local tenderness in the abdomen and nothing whatever to indicate the disease. This silence is only what we might have expected from the analogy of typhoidal and tuberculous ulcerations, which produce in the great majority of cases constipation rather than diarrhea. Thus in only 17 per cent. of the 1.495 cases analyzed by McCrae in Osler's "Modern Medicine" was diarrhea present, though in every case presumably the intestines were extensively ulcerated. The conditions existing in tuberculous enteritis have already been referred to.

Finally we would lay especial emphasis on the fact obvious from the study of the cases in this series, that in many, perhaps most, cases of diarrhea the cause is utterly unknown. No evidence of infection, ulceration, food poisoning, cancer or other disease can be found. In some of these cases we have evidence that the patient has been subjected to unusual overstrain, such as may well have lowered his powers of resistance or upset the vasomotor tone of his splanchnic vessels. Thus loss of sleep and overwork often appear to be causative factors; but the intermediate steps between these strains and the diarrhea are not clearly known.

TYPES AND DIAGNOSIS

Can we recognize what part of the intestine is affected? Many text-books describe symptom-groups supposed to characterize diarrheas originating in the small intestine and in the large intestine, respectively. We have not been able, however, to identify any diarrheas originating in the small intestine. If there is a characteristic symptomatology for such cases we have not been able to find it. As regards the portion of the colon affected by disease one can say only this: that the presence of marked tenesmus points almost certainly to inflammation of the rectum. Beyond this we cannot go with any certainty.

The study of the stools is of much importance, especially in prognosis. Cases in which blood and pus are frequently present in the stools are almost certainly associated with ulcers of the large intestine and run a much more chronic course than those in which blood and pus are absent from the stools. The presence or absence of mucus in the stools seems to be of little importance, especially when there is no other abnormality. Mucus is not proper ground for the inference that enteritis or ulceration is present. In many persons mucus is passed from time to time without any disturbance of the general health and without any known reason whatever.

An excess of fat, starch or protein in the stools is much less often of value in diagnosis or prognosis than the evidences of ulceration just referred to. In the routine examination of stools for causes of diarrhea such an excess of food products is distinctly infrequent and rarely characterizes a case for more than a short time.

Proctoscopy is of great importance in prognosis. The presence or absence of ulceration in the rectum and sigmoid can readily be decided by this method and, other things being equal, a much longer course can safely be predicted in cases showing ulceration of this kind than in those free from it. Thickening and infiltration of the bowel wall may also be recognized in this way and may furnish evidence of a long-standing, relatively intractable process. In nine cases of the Massachusetts General Hospital series the *Amoeba histolytica* was recognized in the stools and led to the identification of amebic dysentery. Such cases, however, are rare in Massachusetts even as importations. In parts of the country in which the *Amoeba histolytica* is common, stool examination may be of the greatest importance as a means of identifying diarrheas of this type, since it may lead to their treatment by the recently discovered specific, emetin.

Diphtheritic colitis or enterocolitis produces no characteristic symptoms and no recognizable abnormalities in the stools. This was proved by the clinical record of diphtheritic cases in which necropsy was performed at the Massachusetts General Hospital.

Mucous colitis or colica mucosa is, in our opinion, not a colitis at all, but a form of neurosis associated with constipation and sometimes with starvation. Of twenty-two cases of this disease studied at the Massachusetts General Hospital in only ten was diarrhea present at any time and, even in those, constipation was much more frequent. As a cause and a result of their neurosis many of these patients have acquired the disastrous habit of examining their stools themselves and it is almost pathognomonic of the disease if the patient produces a bottle in which curious materials have been accumulated as the result of the patient's own study of his dejecta. Habit and the mental attitude are the essential factors in these cases and will be further referred to under the section on treatment.

Prognosis.—The general measure of effectiveness in the treatment of chronic diarrheas of all types may be seen from the following figures drawn from the records of the Massachusetts general hospital: Out of ninety cases of diarrhea lasting over four weeks previous to hospital treatment, there were apparently cured fifty-four, or 60 per cent., and unrelieved (including deaths) thirty-six, or 40 per cent. We have called the favorable cases "apparently cured" because we have not often been able to follow their progress after discharge from the wards.

Further analysis of the results of treatment in twenty-five cases of chronic non-fatal diarrhea averaging about four years in duration shows that chronicity is not necessarily of bad prognostic import. It was found quite easy to check the process and even to cure it in twelve out of these twenty-five cases in which organic ulceration and infiltration of the bowel were not indicated by the presence of blood and pus in the stools or by proctoscopy. Chronicity then, does not necessarily mean intractability. Our fatal cases have rarely been chronic. They averaged less than *four months in duration. In contrast with this* were two cases diagnosed as nervous diarrhea and yielding readily to suggestive therapeutics, though they had lasted two years and five years, respectively.

Of thirteen patients with chronic ulcerated colitis, five were apparently cured, two were improved and six not improved at all.

Acute Diarrheas.—So far as duration measures severity, the non-ulcerated acute cases lasting five weeks or less were as severe as the ulcerated cases. The average duration of seventeen ulcerated cases (with blood and pus in the stools) was fourteen days before treatment began and thirty-eight days after treatment. In twenty-one non-ulcerated cases the average duration was thirteen days before treatment and twelve days after treatment.

The response to our therapeutic endeavors shows that the ulcerated cases were far more intractable. In seventeen out of twenty-one acute non-ulcerated cases, the movements ceased promptly after treatment by rest, diet and catharsis only. Three patients needed also saline irrigations and one bismuth. Opium and silver nitrate were never needed in this group of cases.

Of the seventeen ulcerated cases, on the other hand, only two yielded to rest, diet and catharsis alone. Three of these patients needed opium also, five needed bismuth, seven silver nitrate and eight normal saline irrigations. Three of the seven patients receiving silver nitrate had saline irrigations as well.

TREATMENT

The following experience has been frequently repeated in this series of cases and has left a deep impression on our minds: A patient seeks hospital care with a history of a most obstinate diarrhea which has persisted for months, even for years. He is put to bed in a hospital ward and before treatment is begun the preliminary investigation and preparation of his case occupy probably the first twenty-four hours of his stay in the hospital. During this time the remarkable fact is noticed that he has had no diarrhea, indeed that his bowels have not moved at all. In view of this fact no treatment for the previously troublesome diarrhea is instituted. One waits for the familiar symptom to appear; but it never appears. Day after day passes and finally the bowels have to be moved by enema or by a laxative. At first we interpreted the absence of diarrhea as a cure of the enteritis, but further observation of the patients, after they had left the hospital, showed that in many the diarrhea promptly reappeared as soon as the patient resumed his ordinary habits and occupation. In view of this it seems to us that one must interpret the disappearance of the diarrhea in such cases as due to the remarkable effect of lying in bed. And in fact lying in bed seems to us by far the most efficient and potent remedy at our command in a large number of the acute and the chronic diarrheas. Many of the patients just referred to had been treated unsuccessfully by every known method previous to entering the hospital, but had not remained in bed. That was the one thing that had not been done for them. How far this remedial effect of rest in bed is to be attributed to an effect on the splanchnic circulation we have no means of judging. It is well known that patients with diarrhea become faint, especially during and after the discharges. This faintness is doubtless associated with a low peripheral blood-pressure and it may be that rest in bed raises the average peripheral blood-pressure with a corresponding improvement in the splanchnic circulation. In some of these cases we have demonstrable evidence that the intestinal ulcerations associated with the diarrhea have shown no appreciable tendency to heal, even though the diarrhea itself has been wholly checked as a result of rest in bed.

The good results of purgation in all acute and benign cases are too familiar to need further emphasis. Our experience in this series of cases goes to support the traditional belief that purgation, by means of castor oil or magnesium sulphate, is second only to rest in bed as a remedy for diarrhea. We have seen no special reason to prefer one of these two purges to the other. Either is usually efficient. They are occasionally of value even in cases which have lasted for many weeks. But when definite ulceration is present in the bowel, purgation almost never gives more than temporary relief. Hence, the importance of proctoscopy and stool examination as a guide to treatment.

Diet.—For acute cases, from twenty-four to thirty-six hours' starvation with catharsis is the ideal treatment. Boiled milk has a long-enjoyed reputation, and many patients recover during (perhaps because of) its administration. In chronic cases it is the rule at the Massachusettes General Hospital to give a diet low in fats and carbohydrates.

Irrigations.—Daily irrigation of the lower bowel with warm normal saline solution seems to us of benefit in many obstinate cases. Astringents whether by mouth or by rectum have helped us little. Weak solutions of silver nitrate sometimes produce immediate benefit. If one injection does no good, it is not worth while to repeat it, especially as the remedy is always a painful one and occasionally makes the patient distinctly worse. Quinin injections for amebic dysentery deserve to be given up now that the use of emetin has been discovered. Injections of cooked starch or mucilaginous substances are useful to allay tenesmus.

Olive-Oil.—This substance has distinct value in the treatment of long-standing cases with or without ulceration. It has been extensively used in the Presidio Hospital at San Francisco for obstinate diarrheas in soldiers invalided home from the Philippines. We have used it successfully in doses of ½ ounce after meals in some ambulatory cases of chronicity, but have not yet distinguished the types most benefited or the method of its action.

Psychic Influences.—The good results produced by change of environment are, we suppose, mostly psychic. Morning diarrheas can often be promptly cured by a "change of air" and are sometimes very hard to cure in any other way. How far differences of food and of drinking-water may enter into this result is doubtful.

A most amazing result of a similar "change of air" was seen by one of us in 1898 when the hospital ship *Bay State* took on board from Porto Rican harbors 125 sick Massachusetts soldiers. Practically all of them were suffering from diarrhea of many weeks' duration and had become greatly discouraged and depressed. Within two days of their embarkation on a boat pointed for home, almost every man was free from diarrhea and eating ravenously of the two substances hardest to get in Porto Rico—bread and butter.

Drugs.—The subcutaneous use of emetin in amebic dysentery, as advised by Rogers, seems one of the most brilliant therapeutic results in the history of medicine. Our experience with this drug in a few cases wholly substantiates the reports of Rogers, Futcher, Bass and others.

Of opium we have nothing new to say. We all know its definite though limited value in acute cases, occasionally even in chronic cases to break up a pathologic habit.

Bismuth in doses of from 30 to 60 grains, from once to three times daily, seems to us of value in some obstinate cases when combined with rest and diet. The smaller doses formerly employed do not seem rational and have not been effective in our hands.

Sodium salicylate proved curative in one long-standing case which had resisted many other remedies.

Operation (Cecostomy).—Cecostomy and irrigation of the bowel, through the new hole, has been tried but little in our field of work and our experience does not warrant a definite opinion. Our impressions are not favorable.

1 Marlborough Street—120 East Sixty-Second Street.

ABSTRACT OF DISCUSSION

Dr. W. S. Thayer, Baltimore: Dr. Cabot suggested that in a large proportion of cases of diarrhea it is not possible to say just what the cause is. How are we going to find out? One of the first things we ought to do, a thing which too many of us neglect, is to examine the stools carefully. We can obtain many hints as to treatment from the character of the stools.

I should like to emphasize one of the various causes of diarrhea, namely, a diminished gastric acidity, or anacidity. It is a common cause of rather long-persisting and annoying diarrhea. Annoying diarrheas are relieved by larger doses of hydrochloric acid than are generally given. In many of these cases one may expect to find a large proportion of fatty acid in the stool. We found many cases of imperfect fat absorption associated with diminished gastric secretion. Most of the acute diarrheas are due to greatly varying causes. In a large majority of cases it is impossible to say just what causes the attack.

We are familiar with the nervous attitude of individuals suffering from so-called mucous colitis.

These patients are extraordinarily interested in themselves, and this is an element we have to consider. A nervous element is an associated element, and is not the cause of mucous colitis. The onset of mucous colitis in some instances is almost like that of hay-fever. One of my colleagues whose work as instructor begins in the spring, for three or four years, at about the beginning of May, has become ill with mucous colitis and never recovers until he has finished his teaching in June. When he is suffering from overstrain he has an attack of colitis. In many instances the tendency toward mucous colitis depends on small local foci of infection, and the relief of those conditions is followed by so great an improvement that the mucous colitis recedes to the background. Mucous colitis is also, as Dr. Cabot has said, more commonly associated with constipation, with occasional outbursts of diarrhea, nothing like a continuous diarrhea. The important factor in the treatment of diarrhea of whatever type is rest in bed. It is the hardest thing to do. If we could make our patients go to bed at the outset and stay there for a day or two, often the disease would be ended. For the treatment of cases of subacidity, large doses of hydrochloric acid, from 20 to 30 drops, in a full glass of water, should be given three-quarters of an hour after meals, an hour and a quarter after meals and possibly again after that. The results in some instances are truly miraculous.

Dr. P. S. Roy, Washington, D. C.: I wish to emphasize the giving of hydrochloric acid in diarrhea. Hydrochloric acid controls, in great measure, the opening and closing of the pylorus. The pylorus opens and lets food into the duodenum, and then does not open again until the acid that goes into the duodenum is overcome by the alkalinity of the intestine; therefore, I think that the opening and closing of the pylorus often has a great deal to do with diarrheal attacks. In other words, hydrochloric acid prevents the pylorus from opening and closing too rapidly.

Another point I wish to call attention to is nerve fatigue. Many persons who are not nervous suffer from fatigue diarrhea. The diarrheal attacks which many, though careful in diet and habits, have when attending conventions are largely due to fatigue. I also think that the diarrhea of exophthalmic goiter is a *fatigue* diarrhea. Exophthalmic goiter is nerve fatigue. Rest will therefore do much to correct the diarrhea.

Dr. F. M. Pottenger, Monrovia, Cal.: Frequently when diarrhea develops in a patient having tuberculosis, the attending physician makes a diagnosis of tuberculosis of the bowel and gives a bad prognosis. I often find that it is only a simple diarrhea and that when these patients are put to bed and treated properly the trouble disappears. It is important to bear in mind that diarrhea in a patient with tuberculosis does not mean *dooming* a patient to tuberculous enteritis.

Another factor which should also be understood is that tuberculosis of the intestine is often present when no diarrhea is present. This is shown by Dr. Cabot's charts.

A point on diagnosis: We have made seven hundred examinations of the stools in tuberculous patients and find that about two-thirds of those who have tubercle bacilli in their sputum show bacilli in the feces, most probably from swallowed sputum, whether any symptoms of tuberculosis of the bowel are present or not. This shows definitely that the *finding of tubercle bacilli in the stools of patients having open* tuberculosis is not a diagnostic sign of tuberculous enteritis.

Dr. James S. McLester, Birmingham, Ala.: A form of diarrhea which is becoming increasingly frequent in the South and which is of more than local interest is that which precedes and accompanies pellagra. Not infrequently do we see a patient who first complains merely of diarrhea. Treatment accomplishes little. The following spring or summer other symptoms typical of pellagra appear. By noting the stomatitis and, perhaps, the exaggerated patellar reflex, we can at times recognize this form of diarrhea before the dermatitis develops. Examination of the stools is of no value. Bearing in mind the other nervous symptoms of pellagra, we might class this as a nervous diarrhea, and yet the coincident inflammation of all the mucous membranes suggests enteritis. On the other hand, all of these cases show much lowered gastric acidity—at times complete anacidity—which suggests even another cause of the diarrhea. Occasionally, the administration of large doses of dilute hydrochloric acid will check this distressing symptom of pellagra.

Dr. G. D. Head, Minneapolis: In Minnesota we have been much interested in this group of diarrheas of which Dr. Thayer has spoken. We class these as the achylia gastrica type of diarrheas. We can do much for these patients by giving them large doses of hydrochloric acid.

I wish to ask Dr. Cabot one or two questions. In the first place, I should like to inquire whether or not in this group of cases, that is, the so-called achylia gastrica type of chronic diarrhea, he finds any pathology in the bowel. In the second place, whether or not he finds an achylia gastrica in his cases of exophthalmic goiter with marked diarrhea. We know that in pernicious anemia, with and without diarrhea, there is a high percentage of achylia gastrica, and it occurred to me that the same condition might obtain in the cases of exophthalmic goiter with diarrhea.

Dr. Seale Harris, Mobile, Ala.: There is one form of diarrhea that Dr. McLester referred to, which is of much more frequent occurrence than is generally supposed, and that is the diarrhea of pellagra. I am sorry to say that there are a large number of cases of pellagra that are not recognized, in which the important symptom, and oftentimes the only symptom, is diarrhea.

The Italian death-rate from pellagra, as reported, is less than 4 per cent. In the city of Chicago, in 1911, nine deaths from pellagra were reported. My experience leads me to believe that the death-rate from pellagra in this country is certainly no greater than it is in Italy, and, therefore, in Chicago, or in the surrounding country, from which, perhaps, the cases were referred to Chicago for treatment, there must have been two or three hundred cases of pellagra, most of which were not recognized because the only symptoms were diarrhea and other digestive disturbances. I am sure that in the South and in the South Central states there are a great many cases of diarrhea due to pellagra that are ascribed to other causes.

Dr. H. F. Harris of Atlanta maintains that a large portion of the population in certain sections is suffering from what he calls corn intoxication, in which the only symptoms are diarrhea and other digestive disorders. I have seen a number of cases of pellagra without any skin lesion in which I have made a positive diagnosis, the diagnosis having been based on the diarrhea, the stomatitis, the red glossy tongue and the other digestive symptoms.

In my experience, in at least three-quarters of the cases of pellagra, in which diarrhea is an important symptom, there is lowered gastric acidity or absence of hydrochloric acid. Dr. Clarence Johnson of Atlanta called attention to the fact that in his series of cases of pellagra in which the skin lesions and other symptoms distinctive of pellagra were present and there was absence of or decrease in hydrochloric acid, there was diarrhea, and in those cases in which there was no decrease in hydrochloric acid, there was no diarrhea.

The treatment of diarrhea in pellagra is the same as in diarrhea from any other cause. Rest is most important, preferably in a dark room, because sunlight not only brings out the skin lesions, but also increases the diarrhea and other digestive symptoms.

In cases with gastric anacidity or lowered acidity large doses of hydrochloric acid are indicated. Most important of all is the diet; eliminate the corn products, corn bread, hominy, etc., and confine the diet largely to nitrogenous foods.

Dr. S. Bailey, Mt. Ayr, Iowa: I want to compliment Dr. Cabot for being an iconoclast. I am glad he has the honesty and bravery to attack a popular fad, ptomain poisoning. We have all been extremely disgusted with what we have been told and what we have heard about it. I believe, however, that it will scarcely recover from the body blows which have been and will be inflicted from this time on.

Dr. T. W. Stumm, St. Paul, Minn.: Undoubtedly the most important question to consider will be the cause of the diarrheal conditions. Regarding the cases mentioned by Dr. Thayer and Dr. Head, I should class them as gastrogenic diarrheas. Here in the Northwest we see many of these cases and we usually secure good results in cases of true achylia gastrica by the administration of hydrochloric acid, as Dr. Head suggests.

The other class of cases that we see are the cases of mucous colitis. They are frequently very troublesome. The patient is usually much run down in a general physical way and has been on special diet for months, and possibly for years. I have never seen any good result from placing these patients on a special diet. I am in the habit of telling my patients of this class to eat anything and everything—to take plenty of nourishment—bread, meat and potatoes. There are one or two things which seem to do good in a therapeutic way. One of these is belladonna pushed to the physiologic limit, given either hypodermatically or by the mouth. The second is the injection of cottonseed-oil or olive-oil per rectum; this is to be retained by the patient during the night. Some of the patients will retain a great deal of oil and others will retain only a small amount. This should be taken by the patient in a recumbent position when he goes to bed and as much oil should be injected as can be retained. With these two medicinal measures and a full general diet we can do a great deal for these patients. I class these cases as nervous cases entirely.

Dr. Richard C. Cabot, Boston: Our discussion seems to have centered mostly around two points, the diarrheas associated with achylia and mucous colitis, so-called. I think that the diarrhea of achylia is one of the most interesting types before us, but I do not think that it is nearly so simple as it appears. Take, for example, the achylia of pernicious anemia. That is the best-known form of chronic achylia. Pernicious anemia patients have diarrhea, but much more of the time they do not have diarrhea, and when they are not having diarrhea they do have achylia. The point we ought to realize is that, while achylia is without doubt a factor, it is only one factor. We must find the others before we really know what we are dealing with in these cases.

The morning diarrheas, like the mucous colitis cases, it seems to me, are best treated by the psychic method. I have seen cases of this kind cured more quickly in this way than in any other way. Many cases cannot be cured in any other way. The best kind of psychic therapy here is usually a change of scene with change of water and food—what we used to call a "change of air." I think the change of environment, the psychic change, is the big factor, and reliance on that often brings results just as good as, if not better than, hydrochloric acid does.

A great deal used to be said about degeneration of the gastro-intestinal mucosa in pernicious anemia, but the more these cases have been studied the less it appears that the gastro-intestinal changes are causes. There are no sudden changes in the gastro-intestinal tract in pernicious anemia associated with achylia.

I cannot answer the question in relation to exophthalmic goiter because my experience is limited. In some cases I have found achylia during the period of diarrhea, and in others I have not. I do not know the relation.

Coming back to mucous colitis: I do not suppose that any of us believe in purely psychic causes. We all believe that the body and mind necessarily always work together. When I say that I think that the cause of mucous colitis is a psychic cause, I mean that it is the sine qua non and the factor with which treatment has chiefly to deal. Remove that cause and you cure the patient; if you do not remove that cause you cannot cure the patient. Doubtless there are other factors, but the psychic factor, together with constipation and starvation, as has been emphasized, is the great factor. Some of the most impressive cures I have ever seen have been cures of mucous colitis, in which the patient has been dieted, as the doctor said, in a variety of ways, without any result. The essence of the treatment is encouragement and stuffing.

REPORT OF A CASE OF ACUTE NEPHRITIS IN AN INFANT WITH CONGENITAL HEART DISEASE *

H. M. McCLANAHAN, M.D.
OMAHA

History.—The infant, aged 1 year, came under my care Jan. 4, 1913. Family history negative. Parents both young and in good health. The patient had been a blue baby from birth. Breast-fed for a time. Ever since birth it had had an inspiratory grunt, more perceptible when the child was moved or held erect. Both skin and mucous surface constantly blue. The infant had steadily gained in weight, however, weighing 24 pounds at 1 year of age. Digestion had always been good, bowels regular, urine free.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

History of Attack.—Dec. 5, 1912, infant was suddenly taken sick with sore throat and fever, followed by a general erythematous rash. Later this rash was followed by a series of small vesicles. December 10 some swelling about the face was first noticed. The mother said breathing became more labored and rapid, so that she had to keep the child constantly in a recumbent position. Even then she noticed that the cyanosis was deeper in color. The bowels were regular, urine becoming more and more scanty as estimated by the napkins. Infant was more stupid than usual. Jan. 4, 1913, I noted the foregoing facts as given me by the mother. Temperature 100, pulse, 110, respiration 70. Child vomited two or three times a day while under my care, always after feeding. There were edema of the face, swelling of the arms and legs, and ascites, with pitting along arms and legs. Physical examination of the lungs negative. Pericardial dulness very extensive. Cardiac impulse perceptible. Blowing murmur heard everywhere over heart. Temperature did not go above 100 until a few hours before death. Respirations varied from 60 to 80 per minute.

Examination.—Urine examination January 5. Specific gravity 1.007, acid, albumin by heat and nitric acid, no sugar, no bile. Under the microscope a number of white cells, hyaline and granular casts. January 7: Examination the same with the addition of many blood-cells. Blood examination January 5: Red blood-cells, 8,140,000; white blood-cells, 20,000; hemoglobin, plus. Slight increase in small lymphocytes; otherwise leukocytes normal. January 7: Red blood-cells, 9,800,000; white, 16,000.

Treatment—There was nothing special in the treatment during the time that the patient was under my care. The infant responded well to hot packs. It received sodium carbonate by enema and tincture of digitalis by mouth. General anasarca decreased and quantity of urine increased. There were absolutely no nervous symptoms. Respirations continued rapid. Cyanosis extreme when infant was lifted up. Death was due to apnea.

Clinical Diagnosis.—Acute nephritis due probably to scarlet fever with congenital heart disease. I am satisfied that death was simply hastened by this disease, but was actually due to the heart lesion. In other words, the nephritis was an added burden that the heart could not carry.

Post-Mortem Made Four Hours After Death.—I desire here to thank Dr. L. Moon, intern at the Methodist Hospital, for his very thorough work in preparing the sections from various organs. The body was that of a large, well-nourished infant; slight eruption over body; chest appeared very large, no deformities, skin soft and very dark, mucous membrane dark, muscles flabby, no rigor mortis. Brain not examined. Skin of chest and abdomen quite edematous on incision. Muscles dark red and very soft. No free fluid in the abdominal cavity, no ossification in the costal cartilages. Sternum very soft and porous. Thoracic cavity contained 20 c.c. of light straw-colored fluid. No pleural adhesions. Base of heart at second rib. Apex at the sixth rib. Left border extended outside of nipple line ½ inch. Right border 1 inch to the right of the sternum. Thymus present, but no evidence of pressure on the trachea. Pericardium contained 10 c.c. of clear fluid. No adhesions. The heart was 13 cm. long, 9 cm. wide, 7 cm. thick. It will be noted that this is the size of the adult heart. Heart muscles dark reddish-brown. Cavities contained a large amount of fluid blood. It was noted that there was scarcely any clotting of blood in any organ. Veins of heart greatly dilated. Foramen ovale was open and large; indeed, there was only a light constriction between the auricles, so that both formed practically one cavity. Left auricle was greatly dilated with thin walls. The aortic and pulmonary orifices were smooth and the valves normal. The mitral valve was greatly shortened and thickened, and would not close to exceed one-half of the opening. There was also a defect in tricuspid valve. *Ductus arteriosus* was not found although carefully searched for. Pulmonary vessels filled with blood. It will be noted that there was practically free communication between all the chambers of the heart, no obstruction to flow of blood to lungs and that the aorta could carry a sufficient quantity to nourish the body, but that there was free mingling of the venous and arterial blood. The spleen was dark, congested and very vascular. Bile passages normal. Stomach dilated, also dark in color. Gall-bladder normal. Pancreas hard to touch, and dark in color. Liver 17 cm. long, 7.5 cm. thick, 12 cm. wide, dark in color, greatly congested, bleeding freely on section. Lungs dark in color but no evidence of bronchitis or pneumonia. Left kidney 7.5 cm. long, 5 cm. wide, 4 cm. thick. Right kidney 5 cm. long, 4 cm. wide, 2.5 cm. thick. Both kidneys were firm to touch and dark red on section and showed on section that they were retained by the capsule under pressure, capsule thickened. Bone-marrow of ribs and sternum very dark in color. The entire appearance was one of chronic passive congestion and the great size of the heart and liver was most striking.

Microscopic Findings.—Kidneys show a marked interstitial nephritis with chronic passive congestion. Many cells show hyaline swelling with fatty degeneration, capsule thickened. Marked round-cell infiltration in all fields.

Spleen shows marked congestion with great increase in the connective tissue.

Heart muscle is atrophic with cloudy swelling and evidence of fatty degeneration.

Pancreas shows great increase of connective tissue with marked passive congestion.

Liver capsule thickened, connective tissue increased and marked. Fatty infiltration about the center of the lobules.

Bile ducts dilated and increased pigment.

The pathologist, Dr. W. R. Lavender, reports that the sections of all organs show a passive congestion due to the congenital heart disease, with an acute process due to the complicating nephritis. This is in line with what is usually found in congenital heart disease with cyanosis.

There were two interesting features in the case:

1. Evidence of nephritis occurred earlier than is usual in scarlet fever. From a rather large experience in acute nephritis I think it is fair to assume that death would not have resulted if the infant had been normal. The absence of nervous symptoms with subsidence of the anasarca, increased excretion of urine, all pointed to a favorable termination.

2. The polycythemia. This is the second patient with congenital heart disease in whom I have found polycythemia. I have had the current literature for the last three years carefully reviewed without finding anything on the blood in infants with congenital heart disease. There are valuable contributions on the blood in scarlet fever and whooping-cough, but very little on the blood of infants. It seems reasonable to presume that polycythemia is physiologic in these cases; as the individual cell carries less oxygen, an increase in the number would carry relatively more oxygen. This would seem a reasonable hypothesis.

Brandeis Building.

ABSTRACT OF DISCUSSION

Dr. John Zahorsky, St. Louis: Several years ago I reported a case of polycythemia before the St. Louis Pediatric Society, in which the red cells numbered more than eight million. At that time I looked up the subject, and I am sure I found a condition described in which children with congenital heart disease showed an enormous number of red cells.

Dr. C. F. Wahrer, Fort Madison, Iowa: Is any mention made in the literature that this polycythemia is compensatory?

Dr. H. Lowenburg, Philadelphia: That polycythemia is a symptom of congenital heart disease is true, but it is not pathognomonic. I recall a case in which the count was about eight or nine million and in which there was clubbing of the fingers and a murmnur. This child died rather suddenly and came to necropsy. The heart was found to be normal, but there was a marked chronic interstitial pneumonia. My diagnosis was based largely on the murmur, clubbing of the fingers, dyspnea and polycythemia. I was wrong. The physical signs of interstitial pneumonia were lacking.

Dr. H. M. McClanahan, Omaha: I have looked in the archives for ten years and have found no literature on this subject. All patients with congenital heart disease whom I have ever seen ultimately die of some intercurrent affection. I have had one live to be 16, the oldest patient of whom I have any knowledge. These patients are especially prone to acute infections, and, if they have even a mild infection, it is most likely to prove fatal.

THE NATURE OF ILEOCOLITIS FROM AN ETIOLOGIC POINT OF VIEW*

C. G. GRULEE, M.D.
CHICAGO

The term "ileocolitis," while originally a pathologic designation, has become distinctly clinical. No one, I think, will assert that all cases which show the clinical manifestations of ileocolitis are necessarily combined with the pathologic lesions which the term implies, and certainly not with the severe pathologic lesions which are commonly associated with it. It seems to me that the term ileocolitis conveys to the mind of most persons the clinical picture which follows in from twenty-four to forty-eight hours the acute stage of intoxication of alimentary origin. This period represents a symptom-complex which is more or less regular. The stools, while not so frequent as during the acute stage, contain much mucus and often blood. The temperature ranges usually between 99 and 101 F., prostration is great and the tolerance for food is markedly reduced.

It is this stage of acute attacks of summer diarrhea which offer so much difficulty in the solution of the problem and its cause. In general, three or four processes have been mentioned as possible causes of this condition.

The first is bacterial infection, which has received the greatest prominence at the hands of American pediatricians. "Bacterial infection" here does not mean the intoxication produced by decomposition products, the result of bacterial action on ingested food or its derivatives, but direct infection of the system through the intestinal wall. In this connection, two organisms have been more prominently mentioned, the *Bacillus dysentericus* of the Flexner type, and the streptococcus, and in by no means all of the cases are these two organisms found.

In order to explain the condition as a result of bacterial infection, it has been necessary to resort in some cases to the expedient of assuming that the *Bacillus coli* suddenly becomes pathogenic and causes the symptom-complex which is known as ileocolitis. No one, I think, will deny that no one organism is found in all these cases, nor that exactly the same clinical picture is produced regardless of the organism found in the gastro-intestinal tract. One should make the exception here of certain epidemics which have been reported from time to time, such as those caused by the Shiga bacillus, *B. pyocyaneus*, etc.

The chief reason for claiming pathogenicity for these organisms has been agglutination reactions in the blood. Whether agglutination can be regarded as direct evidence of the pathogenicity of that organism for a patient from whom the blood was obtained seems to me rather doubtful, since we know that such organisms as *B. coli* are agglutinated by normal blood in dilutions as high as 1 to 50. The mere presence of organisms of a doubtful pathogenicity in the feces and intestines of a child sick with ileocolitis certainly cannot be regarded as direct proof of the pathogenic action of these bacteria in a given case, and much more evidence must be brought to prove any such proposition.

The second process also has to do with bacteria, but in a decidedly different manner. In this process the bacteria act as agents decomposing the bowel content—more likely the proteid content of the bowel. The decomposition product thus formed would be regarded as toxic, and such product would produce this condition.

The theory of Kendall is certainly an ingenious one and deserving of our closest consideration. His clinical results, however, are not convincing and it is possible that his failure to obtain altogether satisfactory results may be explained by the fact that the bacteria producing the toxins continue their action below the point where the sugars are ordinarily absorbed and hence have the protein content of the bowel for the medium in which to grow. It should also be borne in mind when speaking of the protein content of the bowel that in the lower bowel this is composed in only a small part, if at all, of the proteid of the food, and there is no reason to think that the decomposition of the mucus produced in the bowel may not be carried on by the intestinal bacteria to as great a degree as is decomposition of the proteid. In this way it is easily conceivable that carbohydrates may increase the proteid content of the lower bowel.

Recent experiments have shown that volatile fatty acids, the product of fat and sugar decomposition, may be distinctly irritating to the intestinal mucosa, one result of which would be the production of mucus.

The third process is that of a metabolic disturbance produced by absorption, either of too great quantities of normal elements, or of elements which, as absorption products, may be regarded as abnormal. The chief advocate of this idea is Finkelstein, and his opinion, in part, is based on the fact that oral or subcutaneous administration of sodium salts or of sugar will produce a rise in temperature. Within the past year the experiments of Samelson, Bendix and Meigs have tended to disprove this theory. They were unable to produce a rise in temperature with sodium chlorid and sugar solutions made up from freshly distilled water. In other words, freshly distilled water did not contain some element which was present in the distilled water which had stood for some time, and this element, at present unknown, was responsible for the production of fever. It might be stated that this element in all probability does not consist of bacterial bodies.

While it has not been possible to produce rises in temperature with the salts and sugars when administered subcutaneously, it has never been disproved that salts and sugars when taken by mouth will produce such rises in temperature, but we must remember that in this case the proposition is an entirely different one. Here the sugars and salts traverse the alimentary canal and are subject to the action of the intestinal ferments and bacteria. It may be that in this instance only more favorable mediums for the growth of intestinal bacteria and the production of toxins are produced. Whatever may be the cause of the fever in this instance, one cannot feel the same security in ascribing to the salts and sugars the metabolic action which many of us have regarded as the potent cause of summer diarrhea.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

The fourth cause which may enter into this, but which probably affects rather the initial stage than the more chronic process, is heat. Just what position heat takes as an etiologic factor in summer diarrhea is by no means definitely determined. It seems reasonably certain that some cases of intoxication are really cases of heat-stroke, but further than this it is impossible to go at the present time.

It seems to me that in the present state of our knowledge it is impossible to decide definitely between these various processes, nor is it possible to assert whether or not the condition is due to the absorption of endotoxins of various bacteria unchanged through the intestinal wall. The fact that the clinical picture does not depend on the type of bacteria found in the intestinal content speaks strongly, to my mind, against the assumption of bacterial infection as a cause of the condition.

The disturbed metabolism as produced by the absorption of sugar unchanged through the intestinal wall is, in light of recent experiments, of rather doubtful value. A more convincing proof will have to be brought forward before it can be accepted as a cause of the condition.

This leaves us with little more than a theory, a theory championed most ably by Czerny and Keller in the discussion of the nature of "toxicosis," a theory which has little to support it in the way of experiments, but against which, at the same time, few objections can be raised.

I am disregarding heat because it certainly cannot be regarded as a prime factor in the later stages of ileocolitis. In considering the condition as an intoxication produced either by absorption of endotoxins or of decomposition products of bacterial metabolism, one must take more account than has been done in the past of the intestinal mucus as a medium for bacterial growth and the source of decomposition products. Theoretically, at least, it would seem that any factor which tends to increase the flow of the mucus, whether in the small or the large bowel, should, if possible, be eliminated.

Perhaps of all the foodstuffs the protein is least irritating and the easiest of absorption, and for this reason, if for no other, it would seem that when food is to be given to infants suffering with ileocolitis, a properly dosed protein food should be the first selection.

122 South Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. R. M. Smith, Boston: I am not yet convinced that bacteria do not play a part in the etiology of ileocolitis. I saw a large part of the clinical work on which Kendall based his conclusions. I feel sure that there is truth in his contention that different types of bacteria contribute to the variety of forms of ileocolitis The different response to different forms of treatment seem to me significant. The response is such as we would expect to receive if different bacteria played a part in the etiology. To illustrate, the cases of the group in which we are in the habit of assigning the dysentery bacillus as a cause respond favorably to the feeding of carbohydrates. We use sugar solution for this feeding. On the other hand, cases of ileocolitis in which the gas bacillus is the etiologic factor do badly when fed with carbohydrates, but do well when fed on a high protein diet. When the food furnished the individual is unfavorable for the development of the particular bacilli present, improvement in the patient is noticed. It seems to me that this different response to different treatment on the basis of a possible difference in bacterial etiology must be considered in this discussion.

Dr. E. W. Mitchell, Cincinnati: We should go away with a mistaken idea if we were to understand that bacteria did not play an important part in intestinal diseases. From the clinical side we have abundant evidence of the great importance of clean milk. By that I mean milk which has a low bacterial count. In my own city there has been an enormous change in the number of cases of sickness in babies in the summer time. I remember well when we attributed ileocolitis and other forms of intestinal trouble to the heat of the summer. Our summers have not changed in temperature; our hygienic conditions have changed for the better; people have learned much about the care of infants, but most important of all, there has been an enormous improvement in the cleanliness of our milk-supply. Those infants whom we feed throughout the summer on certified milk seldom show intestinal disturbance if they have ordinarily good care and if the milk is properly cared for at home. The remarks of Dr. Grulee are exceedingly suggestive as to the probable explanation of those cases which occasionally occur in children receiving a pure milk or children on the breast, and his explanation of why Finkelstein's theory would work out is suggestive. We all have had the experience that when we do use a fat-free milk we have far better results in the prevention of intestinal disturbances and in their more rapid cure. Perhaps Dr. Grulee also suggested a reason for this. In cases of intestinal intoxication it has been the fashion to give white of egg or albumin-water, with sometimes the result of symptoms suggestive of albumin poisoning.

Dr. J. L. Morse, Boston: I feel, as Dr. Smith has said, that our experience in Boston shows that different cases respond differently to treatment. What cures one patient will not cure another. On that basis we do feel that the bacterial etiology is important. It seems to me impossible to draw any absolute conclusions at present because our evidence is not as yet absolute. There is evidence on all sides. How to evaluate that evidence and what conclusions to draw from it has to be a good deal a matter of individual judgment and individual experience. I cannot quite agree with Dr. Grulee that the bacteria do not play an important part.

Dr. Clifford C. Grulee, Chicago: I did not say that bacteria do not play an important part in summer diarrhea. What I did say was that I do not believe that specific bacteria play an important part in summer diarrhea. The bacteria which are frequently accredited with being the cause of summer diarrhea, and especially the dysentery bacillus of the type ordinarily found — that is, the Flexner type, not the Shiga — has not been shown to be especially pathogenic. So far as I have been able to determine there have been a few experiments which have shown the pathogenicity of this bacillus to animals. The antidysenteric serum has proved a flat failure in the treatment of summer diarrhea of infants. The differences in opinion among Dr. Morse, Dr. Smith and myself are differences based on clinical results which cannot be eradicated unless we see the same set of cases. Other men have taken up the work of Dr. Kendall, and I think that I am fairly familiar with that work. I have heard him explain it himself. Others have had no results from the giving of sugar in cases of dysentery. One man followed this out clinicially and did not get the results that had been reported by Kendall. This is easily explained. One can never obtain as good results with a certain method as the originator of that method obtains. In the present state of our knowledge the only evidence of any value that we have for any specific bacterial cause for summer diarrhea comes from the work of Kendall, which is based on the clinical results obtained from different methods of feeding. As yet these results can scarcely be regarded as conclusive evidence.

Importance of the Dispensary.—In view of the vast field that it is called on to cover and the importance of its work, it is a curious fact that the dispensary is looked on almost invariably by boards of managers as the Cinderella of the hospital household. It is scarcely ever cared for properly, is seldom well equipped, and is almost always expected to be self-supporting.—Corwin and Mayo, in *The Outlook.*

ISOLATION OF THE TYPHOID BACILLUS FROM MILK WHICH CAUSED A TYPHOID OUTBREAK[*]

WILLIAM ROYAL STOKES, M.D.
AND
H. W. STONER, M.D.
BALTIMORE

The isolation of the typhoid bacillus from the milk during a milk-borne outbreak of typhoid fever is mainly of interest from the point of view of the general epidemiology of this disease. These findings merely add corroborative details to the well-established fact that milk at times serves as the medium of conveyance for typhoid to various groups of individuals.

The detection of this organism in milk also suggests the adoption of some technical method for the isolation of the typhoid bacillus from this fluid. Such a method, even when perfected, would never be used for the routine examination of market milk. It might, however, be of service in corroborating epidemiologic data in a suspected milk epidemic.

It would not be fitting in this paper to refer to the various milk epidemics of typhoid fever which have been recorded, but reference should be made to the rare cases in which the typhoid bacillus has actually been isolated from milk.

One of the first recorded instances of the isolation of the typhoid bacillus from milk was reported by Konradi,[1] who found this organism in two out of thirty-three samples examined during an outbreak at Kolozsvar. One of these samples was obtained from a bake-shop from which many of the cases originated, and the other sample was obtained from a dairy in which the farmer's son who was milking the cows had a mild attack of ambulatory typhoid fever.

The typhoid bacillus was also obtained by Shoemaker[2] from a specimen of milk which had caused eleven cases of typhoid fever. The various methods used for the identification of the organism are not stated in the article.

EPIDEMIOLOGY

The outbreak of typhoid in which the typhoid bacillus was obtained from the milk occurred in a suburban town in Maryland having 2,500 inhabitants.

In the latter part of July, 1912, 4 cases were noted, and these were followed by 23 cases in August, 19 cases in September and 10 in October, making 56 cases in all. Only 4 deaths occurred. Of the patients 26 were males and 30 were females; 49 were white and 7 were colored. Their ages ranged from 2 to 53 years, the greater number of cases, 5 in each instance, occurring at the age of 12, 17 and 22 years. But ten of the cases occurred in persons beyond 25 years of age.

The usual rate of attack of this town, computed from the years 1909 to 1911, inclusive, gave an average of 15.6 cases of typhoid fever during the four months of July, August, September and October, and, when this is compared to the larger number of 56 cases during the four months of July, August, September and October of 1912, it can be seen that this is an unusual condition, amounting to an outbreak of the disease.

As soon as the unusual number of cases for this town was noted by the State Board of Health, an investigation was begun, and water was soon excluded as a cause, since many of the patients used filtered water, furnished by a water company, which was found to have a very low bacterial count and to contain no colon bacilli. Many hundreds of persons in other towns and villages also used the water at the same time without showing an undue number of typhoid cases. The raw foods were also soon excluded, and it soon became evident that the milk of a certain milkman was the only common food which had been used by most of the victims of the disease.

On inquiry it was found that there were five milkmen serving milk to the citizens of the town and that the four milkmen who served approximately a thousand persons had only six cases on their routes, while the milkman from whose milk the typhoid bacillus was isolated and who served about fifteen hundred persons with milk had about fifty of the cases on his route.

A further investigation disclosed the fact that a woman in the dairy had suffered from typhoid fever two years previously, and that she had been handling the milk and dispensing it to customers. A specimen of the stools and urine was obtained, and from the former a typical typhoid bacillus was isolated. The feces were incubated for twenty-four hours in Conradi's bile-medium and then plated out in the Stokes-Hachtel[3] modified Hesse's medium. Typical concentric pink colonies were obtained, and when these were transferred to culture materials they conformed in all respects to the typhoid bacillus. These organisms were also agglutinated by known typhoid blood and typhoid immune serum, and the fact was thus established that a carrier had been working in the dairy. It was impossible to learn how long before the epidemic this woman had been handling the milk, but she was said to have taken a long rest after her convalescence from typhoid.

Owing to the large number of cases of typhoid fever occurring on the suspected milk route, five samples of milk were secured from the dairy and a thorough examination made for the typhoid bacillus.

TECHNIC

Each bottle of milk was thoroughly shaken and 10 c.c. inoculated into fermentation tubes containing lactose bile. At the end of twenty-four hours plates were made from these tubes on litmus-lactose agar and on the Stokes-Hachtel modified Hesse's medium. After incubation, colonies having the characteristics of the typhoid bacillus on these mediums were fished from the plates and inoculated into fermentation tubes containing dextrose bouillon. In all, about fifty colonies were fished from the various plates. The dextrose broth cultures were incubated for forty-eight hours, at the end of which time all tubes that showed the production of gas were discarded. Those cultures that did not produce gas were stained by Gram's method, and all Gram-positive organisms were next weeded out. The remaining cultures were inoculated on slant-agar, potato, blood-serum, and into litmus milk, stab-gelatin, bouillon and Dunham's peptone solution.

After hanging drops had been studied for motility, and the morphology and cultural characteristics of all the remaining cultures had been observed, only three were sufficiently striking in their characteristics as to be worthy of further study. These were Cultures 5, 9 and

24. These three bacteria were morphologically and culturally like *Bacillus typhosus*. Repeated attempts, however, to secure agglutination with Organism 5 with typhoid immune serum at very low dilutions and with a number of known positive typhoid bloods were futile, and Culture 24 after about ten days developed a fluorescence, and both these organisms were also put aside. Culture 9, however, resembled *Bacillus typhosus* so closely in all its features that a careful study was made of it, which we shall describe in detail.

Morphology and Staining.—The organisms under the microscope appeared as straight rods with rounded ends, occurring singly, from about 1 to 3 microns in length by from 0.4 to 0.7 micron in width. They stained readily by the ordinary anilin dyes, were decolorized by Gram's method and contained no spores. Young agar and bouillon cultures were actively motile.

Cultural Characteristics.—The growth appeared on agar-slants as a uniform layer of translucent grayish-white growth. Bouillon showed a uniform turbidity. Gelatin stab-cultures were not liquefied at the end of six days at 37 C. (98.6 °F.). Litmus-milk showed very slight acidity at the end of twenty-four and forty-eight hours and six days. There was no coagulation. On potato the growth was visible only as a slight glistening moisture. No indol formed in Dunham's peptone solution. Blood-serum contained a uniform growth, the color of the medium. There was no liquefaction.

Agglutination Tests.—Agglutination tests were first made with ten known positive typhoid bloods at a dilution of about 1: 50. The tests were controlled by making similar tests at the same time with Laboratory Stock Culture 4. The results are shown in Table 1.

TABLE 1.—RESULTS OF AGGLUTINATION TESTS MADE WITH POSITIVE TYPHOID BLOODS—DILUTION 1:50

Typhoid Bloods No.	Culture 9 from Milk 24-Hour Bouillon Agglutination	Culture 9 from Milk 24-Hour Bouillon Motility	Laboratory Stock Culture 4, 24-Hour Bouillon Agglutination	Laboratory Stock Culture 4, 24-Hour Bouillon Motility
Controls no serum ..	0	+	0	+

* Slight.

It will be seen from the above table that Culture 9 from milk was agglutinated by nine out of ten positive typhoid bloods, although in two instances there was still slight motility present when the specimens were examined at the end of two hours.

A comparative agglutination test was next made with typhoid immune serum, laboratory stock typhoid bacillus being used as a control. The results are shown in Table 2.

A rabbit was immunized with a vaccine made from Organism 9, from milk, by injecting six doses, the first two of 500 million, the third of 1,000 million, and the last three 4,000 million dead organisms at intervals of ten days between doses.

Agglutination tests were made with serum obtained from this rabbit and twenty-four-hour cultures of Organism 9, from milk, Laboratory Stock Typhoid Culture 4, paratyphoid bacillus (alpha) and paratyphoid bacillus (beta), with the results tabulated in Table 3.

TABLE 3.—RESULTS OF AGGLUTINATION TESTS MADE WITH SERUM OBTAINED FROM IMMUNIZED RABBIT AND VARIOUS CULTURES

* Slight.

The table shows that the serum obtained from the rabbit immunized with Typhoid Bacillus 9 from milk is capable of agglutinizing Laboratory Stock Typhoid 4 at very high dilutions. It also agglutinates both alpha and beta paratyphoid at low dilutions.

Absorption tests were next made by saturating a portion of the serum obtained by immunizing a rabbit with Culture 9 from milk with cultures from Laboratory Stock 4 and Milk Cultures 9. Agglutination tests were made with the serum saturated with Culture 4, with the twenty-four-hour bouillon cultures of both Culture 4 and Culture 9. No agglutination was obtained at a dilution at 1: 20 (lower dilutions were not made). Likewise the serum saturated with Culture 9 was tested for its agglutinative properties by both organisms with like results.

Complement-fixation tests were next made with the serum obtained from the rabbit immunized against Organism 9 from milk, using Laboratory Typhoid Culture 4 as antigen in one set of experiments and Milk Culture 9 as antigen in the second experiment. Complete fixation of complement occurred with Organism 9 from milk with 0.05 c.c. of serum. In the experiment in which Organism 4 was used complete fixation occurred with 0.025 c.c. of the serum.

The bactericidal activity of the serum obtained from the rabbit immunized against Culture 9 from milk was determined for both Organisms 4 from stock and Organism 9 from milk. The experiments were made *in vitro,* according to the method originally devised by Neisser and Wechberg. The results of the experiments are given in Table 4.

TABLE 4.—RESULTS OF COMPLEMENT-FIXATION TESTS MADE WITH SERUM OBTAINED FROM IMMUNIZED RABBIT AND VARIOUS CULTURES

Dilution of Serum	No. of Organisms on Plates Made with Culture 9	No. of Organisms on Plates Made with Culture 4
Undiluted	12,600	4.200
1:2	7,200	8,700
1:4	1,000	8,600
1:8	60	1,800
1:16	0	1,400
1:32	4	600
1:64	2	6
1:128	2	15
1:256	15	5
1:512	1	8
1:1,024	8	300
1:2,048	1,230	900
1:4,096	7,680	3.000
1:8,192	9,600	2,400
1:16,384	5,400	3,000
1:22,768	78,000	3.000

The number of Organisms 9 seeded into each tube, as shown by Control Tube 1, which was not incubated, was 11,000. The number or organisms in Control 2 which was incubated three hours was 60,000. The complement control plate contained 2,000 bacteria.

The number of Organisms 4 seeded into each tube, as shown by Control Tube 1, was 10,000. Control 2, which was incubated for three hours, contained 96,000 organisms, and Complement Control 3 contained 8,500 bacteria.

SUMMARY OF THE SEROLOGIC TESTS

The first set of agglutination tests described in Table 1 shows that the organism obtained from milk would agglutinate with a number of different samples of known typhoid blood, and the tests described in Table 2 show that this organism would also agglutinate in comparatively high dilutions with an immune serum made from a known typhoid bacillus. The agglutination tests described in Table 3 show that a serum prepared by injecting an animal with the organism obtained from milk will agglutinate a known typhoid bacillus in nearly as high a dilution as that obtained with the milk organism itself. This table also shows the phenomenon known as the "group" agglutination, since it can be seen that the milk typhoid serum will agglutinate both the alpha and beta paratyphoid bacilli in low dilutions.

The absorption tests made by saturating the serum of the animal immunized with the culture obtained from the milk show that the antigen prepared from the typhoid bacillus obtained from milk is capable of binding all of the typhoid agglutinogen or receptors with which the agglutinin combines. When these receptors had combined with all of the agglutinin in the blood-serum, this serum was no longer able to produce agglutination of a known typhoid bacillus or of the suspected typhoid bacillus obtained from the milk.

The same experiment was performed by using a known typhoid bacillus as the antigen, and all of the agglutinin was again abstracted from the immune serum made from the milk typhoid bacillus.

The complement-fixation tests also show that the antigen made from the typhoid bacillus obtained from the milk, as well as from a known laboratory typhoid bacillus, was able to produce complete complement-fixation by combining with the amboceptor in the immune serum made from the milk typhoid bacillus.

The bactericidal tests described in Table 4 show that the amboceptor contained in the immune serum made from the milk typhoid bacillus is able to bind the complement to known typhoid bacilli as well as to the milk organism, producing marked bacteriolysis in the dilutions, which are set forth in the table. The failure of the lower dilutions to destroy the typhoid bacillus in both cases corresponds to the phenomenon already described by Ehrlich and known as the "Neisser-Wechberg phenomenon." In this reaction when an excessive amount of amboceptor is used the complement is not bound to all of the typhoid bacilli, and these escape destruction and later multiply rapidly.

These experiments, therefore, show that the antigen of the milk typhoid and the antigen of the known laboratory typhoid bacillus correspond in all of their serologic characteristics and completely confirm the cultural tests, which are all characteristic of a typical typhoid bacillus.

PATHOGENIC PROPERTIES

In order to test the pathogenic properties of the typhoid bacillus isolated from milk the organism was injected into the peritoneal cavity of three guinea-pigs. A quantity equivalent to about 4,000 million live typhoid organisms from a twenty-four-hour growth on blood-serum was used for injecting each animal. It is a well-known fact that the typhoid bacillus is often variable in its effect on animals, and this organism did not prove to be very virulent. Two of the guinea-pigs recovered from this injection, but the third animal died in twenty-four hours, and the necropsy showed an extensive fibropurulent peritonitis. Cover-slips from this exudate showed nothing but Gram-negative, typhoid-like bacilli and a few pus-cells. Cultures from the peritoneal cavity, the liver and the spleen showed numerous colonies of the typhoid bacillus. The injection in this one animal, therefore, produced purulent peritonitis and a general bacteriemia, thus showing that the organism was pathogenic.

METHODS USED TO CONTROL THE EPIDEMIC

After the discovery of the carrier case in the dairy the place was closed, September 28, and in about ten days from this time the epidemic had practically ceased. It should not be thought, however, that this result was entirely due to this one act, since an investigation of the water-supply of a certain percentage of the citizens showed a most remarkable condition of affairs. These persons obtained their drinking-water not from the water company furnishing pure water, but from shallow or deep wells, almost all of which were polluted either by adjoining cesspits or box toilets.

A large number of chemical and bacteriologic examinations of water were made and almost all of the wells were found polluted, either bacteriologically or chemically. These examinations were made from September 25 to October 21, inclusive, and it can be seen that the epidemic had then already been under way for two months. Owing to this reason it is very difficult actually to separate the water-borne from the milk-borne cases; but the almost exclusive distribution of the cases to one milk-route would seem to indicate that the typhoid bacilli from these cases had not penetrated the soil to a sufficient extent to actually introduce typhoid bacilli into many of the drinking-wells.

After having discovered the remarkable condition of saturation of the subsoil with the seepage from the cesspits it was determined to disinfect these pits by calcium hypochlorite. It was found that there were two hundred cesspits in this small town, and about 20 pounds of calcium hypochlorite were added to each one of these pits. The pools and gutters in the town and on the outskirts were also disinfected.

It is impossible to say whether or not this disinfection had its share in stopping the outbreak, but it seems reasonable to believe, from the results of the chemical and bacteriologic examinations, that there must have been fairly constant communication between the polluted material in the pits and the drinking-water from many of the wells. At least, the epidemic practically ceased after the first week in October, and the removal of the carrier case from the dairy, as well as thorough disinfection of the cesspits, can both be regarded as having aided in preventing the further spread of the disease. The handles were removed from most of the pumps connected with these drinking-wells, and this also had its effect in preventing the further spread of infection.

SUMMARY

1. The first point of interest in this study consists in the isolation of a typical typhoid bacillus from the milk which caused a milk-borne outbreak of typhoid fever.

2. The study is also of interest as demonstrating the relation of infected milk to the epidemiology of typhoid, and contains the methods by which the cause of the outbreak was recognized and by which its further spread was averted.

We are indebted to Drs. Frederic V. Beitler, C. W. G. Rohrer and W. B. D. Penniman for much information and aid in preparing this paper.

THE TREATMENT OF DIPHTHERIA CARRIERS [*]

HENRY ALBERT, M.D.
Professor of Pathology and Bacteriology, University of Iowa; Director of the Bacteriological Laboratory, Iowa State Board of Health.
IOWA CITY, IOWA

In this paper I shall consider the treatment of diphtheria carriers with the idea of ridding them of the specific germs. The paper will not comprehend the treatment of the diphtheria patient nor will it deal with the problem of isolating or otherwise protecting others from the carrier.[1]

The necessity for the treatment of carriers with the idea of getting rid of the diphtheria bacilli is obvious when we consider the frequency of the carrier condition and the length of time that the condition often continues. After the clinical symptoms of the disease have disappeared, the patient is ready to be released from quarantine, but the interests of the public health demand that he shall not mingle with the general public while he still carries the germs of the disease.

NUMBER OF DIPHTHERIA CARRIERS

According to Ledingham,[2] 50 per cent. of persons affected by diphtheria have lost the bacilli by the time the local membrane has disappeared. Of those harboring diphtheria bacilli after the throat had become healthy in appearance, Scheller[3] found that 77 per cent. still had the bacilli at the end of eleven days after the throat had become normal in appearance; 35 per cent. at the end of twenty-one days; 18 per cent. at the end of thirty-one days; 5 per cent. at the end of two months, and 2 per cent. at the end of three months. Considering that these figures apply only to the 50 per cent. of patients who still have diphtheria bacilli after the throat has become clear, it means that if we took as a basis the total number of cases of diphtheria, the percentage figures would be only one-half those given. My own figures are slightly different.[4] I found that of all cases of diphtheria, 41 per cent. were free from diphtheria bacilli by the end of the second week after the beginning of the disease; 73 per cent. at the end of the third week, and 99 per cent. at the end of the fourth week.

Of the general population who have not been affected by the disease, 1 or 2 per cent., under ordinary conditions, and from 5 to 10 per cent. during epidemics of the disease are "carriers" of the germs. They retain the bacilli for about the same length of time, on an average, as convalescents from the disease.

VIRULENCE OF BACILLI IN CARRIERS

The virulence of the diphtheria bacilli seems to be but slightly lessened during the carrier condition even though the condition persists for a long time and is completely lost (as determined by the ordinary tests) in only a small proportion of the cases. It is therefore quite obvious that with but few exceptions a carrier can transmit the disease as long as the carrier condition remains. It is also probable that the carriers are responsible for more cases of the disease than are those affected by the disease itself. This certainly seems to be the case if we include among the carriers those with slight evidence of local inflammation, but presenting no obvious general symptoms and whose condition is not diagnosed clinically as diphtheria.

LOCATION OF THE BACILLI IN THE CARRIER

In general we may say that the nose and throat are the places in which the diphtheria bacilli are to be found. On that basis, the release from quarantine for diphtheria is based, almost the country over, on negative findings of swabbings from the nose and throat. Swabbings taken from both and cultivated separately indicate that, when dealing with well persons, the bacilli are found more frequently in the nose than in the throat.[5] These findings are the results of surface swabbing. The result will probably be different, if the swab, instead of being used on the surface of the tonsils, is introduced into the crypts of those structures.

It seems improbable that the diphtheria bacilli will remain and continue to grow for any great length of time on the rather smooth mucous membrane which covers the greater part of the nose and throat; rather do I believe that their home is in little pockets here and there from which there is not a sufficient stream of mucus to dislodge them. Such pockets may be represented by the crypts of the tonsils, the fissures of the adenoids, the spaces about the turbinates, and the sinuses connected with the nasal cavity.

The finding by Beyer[6] of diphtheria bacilli in the urine in every one of nineteen children examined from four to fourteen weeks after they had apparently recovered from diphtheria should cause further investigations of this phase of the subject. If his report is generally confirmed, it will have an important bearing on public health, especially with reference to milk.

METHODS OF RIDDING CARRIERS OF THE BACTERIA

Many methods have been used to get rid of diphtheria bacilli. These have consisted of liquid antiseptics applied with cotton, sprayed or gargled; inhalations of antiseptic vapors; use of diphtheria vaccine, toxin, antitoxic and antibacillary serum, toxins of the *Bacillus pyocyaneus*, and finally the use of cultures of staphylococci.

1. *Use of Liquid Antiseptics Applied by Means of a Cotton Swab.*—These are applied, of course, only to the throat (tonsils and pharynx). They consist of such liquid antiseptics as a weak solution of phenol (carbolic acid), glycerin, with 3 per cent. iodin, and 5 per cent. solutions of silver nitrate. As ordinarily performed, the antiseptics are applied only to the exposed surfaces of the throat, no effort being made to get into the crypts of the tonsils. I shall refer to these later.

---

2. *Use of Liquid Antiseptics Applied by Means of a Spray.*—These may be applied to both nose and throat. The following fluids have been used with greatest success: Seiler's solution; Dobell's solution; hydrogen peroxid of 0.5 per cent. (by weight) strength. Any of these solutions are found to be too irritating for many persons.

It is probable that sprays are more efficacious than liquids applied by means of a swab in the ordinary way. Nevertheless sprays do not reach the recesses in which it is most probable that diphtheria bacilli find their hiding-places.

3. *Use of Liquid Antiseptics Applied by Means of Gargles.*—These are probably more effective for the throat than either swab applications or sprays. The liquid that has probably given the best results is hydrogen peroxid in from 0.5 to 1 per cent. strength (the ordinary commercial hydrogen peroxid solutions are of about 3 per cent. strength). Solutions of sodium chlorid and Seiler's solution have also been used. The liquid used as a gargle may also be used as a mouth-wash.

4. *Inhalations of Antiseptic Vapors.*—The following method was used by the French army, in 1910, for the disinfection of the nasopharynx: A mixture is prepared of iodin, 12 gm.; guaiacol, 2 gm.; thymol, 25 gm., and alcohol (60 per cent.) 200 c.c., to which are added 6 gm. of potassium iodid to aid in the dissolving of the iodin. This mixture is placed in a porcelain dish and the dish floated in a basin of boiling water. The person whose nasopharynx is to be disinfected should sit with head bent over and nose a few inches distant from the porcelain dish, and inhale the fumes by breathing slowly through each nostril. There should be five sittings in twenty-four hours, each sitting to last two or three minutes. I have not yet seen any statistical data of the effect of this inhalation treatment on diphtheria carriers. This and other inhalations are worthy of much more extensive trial.

5. *Diphtheria Antitoxin.*—The use of antitoxin administered either by hypodermic injection or by the dissolving of tablets in the mouth seems to have no effect in getting rid of the bacilli.

6. *Antibacillary Diphtheria Serum.*—Some good results have been reported from the use of antibacillary diphtheria serum applied locally. The evidence of its value is, however, very unsatisfactory.

7. *Diphtheria Vaccine.*—Vaccines of dead diphtheria bacilli were first used with the view of curing the carrier condition by Petruschky[7] in 1908. Five of his six cases seemed to respond favorably to the treatment. Similar results suggesting that vaccines are of some value were obtained by Hall and Williamson[8] in 1911 and by Forbes, Duncan and Newsholme[9] in 1912.

8. *Diphtheria Toxin.*—Hewlett and Nankivell[10] report a reduction in the time that diphtheria bacilli can be found in the nose and throat after an attack of the disease by the hypodermic injection of diphtheria endotoxin, beginning with a dose of 2 mg., followed at the end of a week or ten days, if necessary, with an injection of 5 mg.

9. *Staphylococcic Culture (Living) Sprayed into Nose and Throat.*—In December, 1909, Schiötz,[11] a Danish physician, described a method of freeing throats from diphtheria bacilli which seems destined to be a procedure of considerable importance. It has proved successful in about forty reported cases in which other measures failed, and so far no unfavorable results have been reported. Schiötz obtained his suggestion from the fact that a person with a staphylococcic sore throat placed in a diphtheria ward under a mistaken diagnosis did not contract diphtheria. He also found that the germs disappeared on the development of an ordinary staphylococcic sore throat, from several patients in whom, after recovery from diphtheria, the specific bacilli persisted for some time. He reported the treatment of six cases with the staphylococcic culture obtained from the throat of a healthy person. The diphtheria bacilli disappeared after one inoculation of the throat of a man who had been detained in the hospital for three months as a diphtheria carrier, and of a woman who had likewise been detained for two months. The other patients who had had diphtheria more recently recovered from the carrier condition with equal rapidity after one treatment with staphylococci. More recently Page[12] tested the method with equal success. Catlin, Scott and Day[13] tried the staphylococcus spray on carriers in connection with an epidemic of diphtheria which occurred at the Rockford (Ill.) hospital. Of seventy persons, 17 per cent. developed diphtheria and 31 per cent. became carriers. In spite of liquid antiseptic treatment, some of them continued to remain carriers for a long time, but the bacilli soon disappeared after the use of the staphylococcus spray. Lorenz and Ravenel[14] also report good results in a few cases. Alden[15] of our laboratory reports good results in fifteen out of sixteen cases. The material used was a broth-culture of the *Staphylococcus pyogenes aureus* which was originally obtained from a throat culture submitted for examination for diphtheria bacilli. The inoculated broth tube was kept in the incubator at 37 C. (98.6 F.) for eighteen hours. The treatment consisted of sprays of the living staphylococci into the nose and throat. Treatments were given once a day until the patients were free from diphtheria bacilli.

Lydia Dewitt[16] in making an experimental investigation of this method of treatment was unable to determine to what influence the good effects are due. There is apparently no antagonism between the two organisms.

Aside from the occurrence of slight negligible reactions, the literature contains no reported cases of harmful effects produced by the use of the staphylococcus spray. I desire to report one case of this kind, which occurred in the practice of Dr. J. E. Luckey of Vinton, Iowa, with a culture supplied by us. He reports:

> We used the culture of staphylococci in two cases. Our first case responded beautifully, the bacilli disappearing in a few days. The second case cleared readily of the Klebs-Loeffler bacilli, but the reaction, consisting of local inflamma-

tion with nausea, chills, high fever and rapid pulse, was so great that we desire to be excused from its use in the future.

The development of this severe condition may, of course, be a coincidence.

10. *Extirpation of the Tonsils when Markedly Enlarged and Removal of Adenoids.*—These conditions alone are indications for the operative procedures mentioned. The continuance of the diphtheria-carrier condition represents a further indication. On account of the wound produced, it is advisable to give an immunizing dose of diphtheria antitoxin before the operation, as cases of severe diphtheria in carriers following such operations have been reported.

AUTHOR'S EXPERIENCE AND EXPERIMENTS AS TO THE PRESENCE OF THE DIPHTHERIA BACILLI OF CARRIERS IN THE CRYPTS OF THE TONSILS

Discovery of the Crypts of the Tonsils as the Hiding Place of Diphtheria Bacilli.—During the spring of 1911 a number of cases of diphtheria occurred among the nurses and patients of the University Hospital at Iowa City. As it was suspected that some of the nurses or other employees of the hospital were diphtheria carriers an examination was made of the nose and throat of every employee in the hospital with the result that twenty-two of them (20. per cent. of the entire number) proved to be carriers. These were placed in isolation, the nose treated with an alkaline antiseptic spray and the throat gargled with a 1 per cent. solution of hydrogen peroxid. The desire for the inmates to be released from isolation as soon as possible caused eight of them to use a hydrogen peroxid gargle *within fifteen minutes* of the time that the culture was to be taken. The person who took the culture was apprised of this fact and consequently took two swabbings from each throat, one from the surface of the tonsils and pharynx and one from the crypts of the tonsils. In all but three of these cases, cultures from the surface swabbing did not contain any diphtheria bacilli, whereas, in every instance but one, cultures from the tonsillar crypts were positive. This indicated that so far as the throat is concerned, the crypts of the tonsils are the hiding-places for diphtheria bacilli.

Other Evidence Implicating the Tonsillar Crypts in Connection with the Carrier Condition.—Aside from the observation just noted, which I have noticed on a number of occasions subsequently, I may mention that:

1. The tonsils seem to be the logical place in which diphtheria bacilli should remain, in view of the fact that they are the parts most often primarily affected by diphtheria.

2. The surface being smooth and having mucus, saliva, etc., passing over it more or less constantly does not seem to be a favorable place for diphtheria bacilli to remain and multiply unless, of course, a membrane has formed. On the other hand, diphtheria bacilli or any other bacteria that have once gained entrance to the larger crypts, some of which are more than a centimeter in depth, find it a place in which they are but little disturbed, lined as these crypts are by squamous epithelium and not giving origin to any secretion or excretion to sweep the contained bacteria out, as occurs in connection with the ducts of glands.

3. Those who have had extensive experience with diphtheria-bacilli carriers report that a large proportion of them (considerably larger than among those who are not carriers) have enlarged tonsils with prominent crypt openings and deep crypts.

4. By squeezing the tonsils and forcing "plugs" of material out of the crypts, Kretschmer[17] has succeeded in freeing thirteen patients from the carrier condition on whom the more simple measures failed.

5. Treatment aimed at destroying the bacteria in the tonsillar crypts has proved successful in ridding diphtheria carriers of the contained bacteria. Although silver nitrate has long been used to treat inflammatory conditions of the throat, its use for treating diphtheria carriers whether there was naked-eye evidence of tonsillitis or not was first used, so far as I know, by Dr. L. W. Dean of Iowa City. He tried it first on the University Hospital employees in 1911. The carriers in question had been treated from three to ten days with antiseptic sprays and gargles, during which time only two of twenty-two carriers became negative. Of the remainder, fourteen had the crypts of their tonsils treated with silver nitrate. Of the cultures taken twenty-four hours later ten were negative. The remaining four became negative within three days. A number of physicians to whom I have recommended this treatment, have informed me that this method has yielded better results than any other method tried including the staphylococcic culture method (Luckey).

Method of Applying the Silver Nitrate.—A 5 or 10 per cent. solution is used and should be made up with distilled water and kept in a dark-colored bottle or a dark place to prevent deterioration. This solution is applied by means of applicators made of a metal which may be bent readily as copper and are long enough (about 11 inches) to admit of convenient handling. The end which is to be inserted into the crypts must be small (about 0.75 mm. in diameter) and roughened in order to hold cotton. Around this end is tightly wrapped a very small amount of cotton—only a few fibers, so that the cotton-wrapped applicator measures less than a millimeter in diameter. This is bent about a centimeter from the end so that the angle formed is a little more than 90 degrees. It is then dipped in the silver nitrate solution. All excess of the solution should, however, be removed by pressing the cotton against the inner side of the neck of the bottle. This is important since the excess may trickle down the throat to the glottis of the larynx where the reaction induced may prove serious. With the tongue well pressed down, the crypts should be probed preferably from below upward, since the slight amount of silver nitrate which may not enter the crypt tends to flow down and the whitening produced tends to obscure the openings of crypts below. The openings of the larger and therefore most important crypts are easily found and entered. To find the smaller ones it is often necessary to run the end of the applicator gently over the surface of the tonsil until it finds a depression. Several of the smaller ones may be probed without redipping the applicator into the nitrate solution. For the larger ones it is best to redip each time. If the cotton-wound probe is too thick, it will not readily enter the crypts. In that case the applicator without the cotton will often pass in easily. Without the cotton, however, it is impossible to introduce sufficient of the nitrate solution, unless possibly the applicator is sufficiently roughened just back of the tip to "hold" a little fluid.

The Effect of Silver Nitrate Applications.—Bacteriologic: The 5 per cent. solution of silver nitrate will destroy all bacteria with which it comes in contact. I have been unable to obtain a culture from many crypts that were thoroughly treated with silver nitrate from which I had just previously obtained cultures of the diphtheria bacillus and other organisms. This, then, is one way in which this treatment of the crypts gets rid of diphtheria bacilli.

---

[17] Kretschmer, M.: Zur Bekämpfung der Bacillenpersistenz bei Diphtheriere-konvaleszenten, Med. Klin. 1911, vii, No. 3.

Pathologic: The silver nitrate solution (from 10 to 40 per cent.), if thoroughly applied, will destroy the lining epithelium of the crypts. If not thoroughly applied, the deeper epithelial cells are not destroyed. In any case there is an inflammatory reaction, the degree depending on the strength and amount of the solution. I have tried solutions up to 40 per cent. Although the stronger solutions produce more destruction of tissue and are therefore better, if that is what is desired, yet the reaction induced is often too severe. I believe, therefore, that the weaker solutions (from 5 to 10 per cent.) are the better. Microscopically the reaction consists principally of a hyperemia, a leukocytic exudation and a proliferation of fibroblasts.

The pathologic changes induced are probably of benefit in two ways:

1. The destruction of the epithelium of the crypts and the accompanying fibroblastic proliferation tends, no doubt, to obliterate the lumen of the crypt, which is quite obviously desirable.
2. The greater number and activity of the leukocytes renders greater phagocytosis possible, and the hyperemia brings to the area the antitoxic, bacteriolytic and opsonic properties of the blood. It is quite probable that the good effect of staphylococcic cultures is due to the induction of a similar reaction.

Clinical: My experience has assured me that the application of a solution of silver nitrate to the crypts of the tonsils is efficacious in ridding diphtheria carriers of the specific micro-organism. I believe that its use is more efficacious and less dangerous than the use of the staphylococcic culture; in other words, I believe it to be the best single remedy which we have.

CONCLUSIONS

1. The length of time during which patients who have had diptheria continue to carry diphetheria bacilli in the nose and throat after all clinical evidence of the disease has disappeared, and the frequency with which diphtheria carriers are found among persons who have never had the disease, renders it important in the interest of both the individual and the public health to rid carriers of the specific organisms as quickly as possible.
2. It is obvious from the large number of methods proposed for the removal of diphtheria bacilli from diphtheria carriers that no one method has proved satisfactory.
3. The use of the various antiseptics, gargled or sprayed, is of doubtful value in relieving the carrier condition, although they no doubt destroy many of the germs with which they come in contact and therefore lessen the infectivity of the carrier.
4. During the past few years, good results have been obtained by myself and a number of other observers, by the use of a spray of a culture of staphylococci.
5. I have obtained my best results by the treatment of the crypts of the tonsils with a solution of silver nitrate (from 5 to 10 per cent.) applied by means of a thin flexible applicator, combined with a mild alkaline and antiseptic spray (such as Seiler's solution), for the nasal cavity, and a 1 per cent. solution of hydrogen peroxid as a mouth-wash and gargle.
6. There is great need of applying the different methods of treatment aiming at ridding diphtheria carriers of the specific micro-organisms in a well-controlled manner in a large series of cases.
7. If it is found that diphtheria bacilli are frequently found in the urine of convalescents, more attention should be given to the hygienic aspects connected with this condition.

I desire to acknowledge the courtesy of Dr. L. W. Dean of Iowa City in supplying me with tonsils treated with solutions of silver nitrate of different strength at varying lengths of time preceding their removal.

ABSTRACT OF DISCUSSION

Dr. L. L. Ten Broeck, Minneapolis: The application of antiseptics to tonsillar crypts is an advancement over methods previously employed; it is also an acknowledgment of its shortcomings, to-wit, the difficulty of controlling the entire infected area. Reports based on cultural control alone may be misleading, since the areas accessible to culture are necessarily limited to areas accessible to antiseptic application. It is the inacessible areas and crypts that justify such methods as those of Scholtz (staphylococcus) or Emmerich (pyocyanase). The use of facultative pathogens, especially on raw surfaces in acute stages, is open to criticism, for postdiphtheritic staphylococcus infiltrations are not unknown. Furthermore, the bactericidal action of an organism is not demonstrated by spraying it copiously on a diphtheritic field, even if culture on mediums supporting well the growth of the sprayed organism subsequently fails to develop colonies of *Bacillus diphtheriae*. To illustrate, Dr. Corbett, city bacteriologist, found nothing but streptococci in a postdiphtheritic otitis medium. Dilute phenol irrigations, however, inhibited this growth and permitted pure cultures of *B. diphtheriae*. Subsequent mixed inoculations gave streptococci only. Given a medium supporting the *B. diphtheriae*, and not its antagonist, grow the two together on mediums suitable to both and one has an absolute test of the bactericidal properties of the antagonist. For example, here is a broth culture (exhibiting the same) of *B. diphtheriae* to which on the second day were added a thallophytic fungus (genus *Saprolegnia*) and human blood (since the fungus grows only on human blood so far as ordinary culture mediums are concerned, not on Loeffler's mediums.) Subcultures the third day on Loeffler's, likewise the fourth day (that is, from the inoculation with *B. diphtheriae*) are negative as you see in these tubes. Clinical tests have been made on normal throats, in twenty-five cases of follicular tonsillitis and in fifty cases of membranous tonsillitis without complications traceable to the fungus and with disappearance of the diphtheria germ in about seventy-two hours in cases controlled bacteriologically. A few patients have made a clinical and bacteriologic recovery following inoculation with the fungus alone without other medication. This (exhibiting specimen) is a diphtheritic cast of a uvula removed without recurrence sixty-eight hours after diagnosis and inoculation with the fungus, cultures remaining positive for three days only. Four membranes have been removed from four diphtheritic patients and inoculated on normal throats about twelve hours after use of fungus on patients. A slight faucial congestion negative for diphtheria was all that was noted, the thallophyte apparently growing to the exclusion of other contagion. Perhaps it will be possible to compel the patient to transmit the prevention as well as the contagion even at this early stage. The dispensing is simple —a powder, kept in vials, consisting of spores lactose (a diluent) and blood on which it is grown and from which it is filtered. These statements are based on results that are at present undergoing critical review in the University of Minnesota. A report will be forthcoming as soon as they are substantiated.

Dr. Henry Albert, Iowa City, Iowa: Were cultures made after forty-eight hours following the use of the spores?

Dr. L. L. Ten Broeck, Minneapolis: Yes; cultures were made up to four days. The test has been repeated with a number of strains.

Dr. Harold B. Wood, Rochester, Minn.: Just because the diphtheria bacilli finally give way to staphylococci in the throat is no specific reason why only the staphylococci themselves should be used as overriders. After Ravenel put that theoretic transference into the practical experience of using the staphylococci as overriders to eliminate the diphtheria bacilli, all or practically all the experimenters seemed to be using the same organism. That organism is well known to be a facultative pathogen. Some other organism which cannot damage the human body would perhaps be the more ideal organism to use in overriding.

I have one report which is so brief that no conclusions can be drawn from it; however, it may be of interest. At Rochester we have recently (this year) been using the lactic acid bacillus as an overrider. Four cases of diphtheria appeared in the state insane hospital. The cases had absolutely no direct connection one with another; but it was found that they had an indirect connection with a certain kitchen. Cultures were made from all of the help of that kitchen and one woman, who had never had any symptoms of diphtheria, was found to be the carrier. Her throat was swabbed and sprayed with various antiseptics of different strengths, and repeatedly, for six weeks, gave positive cultures. Then, at the suggestion of Dr. A. H. Sanford, bacteriologist to the Mayo Clinic, the lactic acid bacillus spray was used. The lactic acid bacillus is harmless, undoubtedly, to human beings; it is easily obtained and is a rapid grower. This spray was used for several days and then, two weeks after that, the woman was examined for the first time and gave negative cultures. About three weeks ago our next cases of diphtheria appeared. Four patients were given antitoxin, their throats swabbed out with tincture of iodin, and no effect obtained in neutralizing the diphtheria growth. Three sprayings were given each person within thirty-six hours, and every subsequent culture was negative. One case was especially severe: A young man came from South Dakota with a well-advanced case of diphtheria. His entire pharynx was blocked with membrane, and within thirty-six hours he was given twenty-eight thousand units, with no effect except to check the increase of the membrane. His throat was swabbed with pure tincture of iodin a number of times without effect; but after being sprayed with the lactic acid bacillus three times within thirty-six hours the membrane showed rapid decrease, and within three days it had entirely disappeared. Before the spraying, all the cultures had been positive; after spraying all were negative. These results are simply suggestive, but are offered that the plan may be carried out by others who have greater opportunity for work. There is one practical point in this connection: If a country physician finds a case of diphtheria and if he is without antitoxin or antiseptics, it would do no harm, and might do good, to flush the nasal cavity and the throat thoroughly with ordinary sour milk.

Dr. D. L. Richardson, Providence, R. I.: We have tried all kinds of solutions in the treatment of diphtheria-carriers with about the usual results. We have used silver nitrate solution, staphylococcus spray, iodin, iodin and glycerin, peroxid of hydrogen and bichlorid of mercury as applications to the fauces, to the throat, to the nasopharynx and to the nose, and we have come to the conclusion that cases should be left alone for a certain period of time, no applications being used except some mild solutions when there is a marked nasal discharge. After a certain period, if the cultures continue to be positive, we generally make application of tincture of iodin or of iodin and glycerin. If this, however, proves of no value, we have for eighteen months removed adenoids and tonsils. This latter is, judging from our own experience, a most efficacious method of getting rid of diphtheria bacilli in persistent carriers. Once in a while, we will fail, but I think less frequently than with any other method of treatment. Remember that in getting rid of the foci of infection, the adenoid tissue and tonsils, we have removed the deep infection which local applications could not reach. Then, if overriding with staphylococcus spray is theoretically or practically of any value, by the operation you have infected the throat with the organisms resident in that throat. Whether it is this or the removal of the adenoids and tonsils that rids the throat of the different organisms, I am not sure. I do know that in England they are removing adenoids and tonsils for this purpose. After operation and until discharge, there is little danger of the throats picking up other organisms, whether diphtheritic or otherwise; but it is our custom to quarantine all such cases so long as the throat shows any active inflammatory result after the operation or until the patient is discharged.

Dr. C. Hampson Jones, Baltimore: In Baltimore we have tried to solve this question not only in the use of all kinds of antiseptics, but also in trying to determine whether or not it is necessary to use anything to clear up the throat.

Drs. W. L. Moss and Guthrie of the Johns Hopkins Hospital carried out a series of experiments during the past twelve or eighteen months. I know that from fifty positive throats that were followed day after day and week after week there were absolutely no cases of disease produced. . . . Exactly what it means we do not know. Of course, Dr. Moss and Dr. Guthrie and others have worked out the strictly scientific end of it, so far as the bacteriology is concerned, and no doubt their report will be found of great interest.

There is one method of clearing up the throat not mentioned to-day, that might be of service somewhere, that is, the use of iodin. The iodin we use is known as Boulton's solution of the national formulary—a combination of phenol (carbolic acid) and iodin—which clears up the throat wonderfully well; but the preliminary spraying of the throat with cocain and going over the throat with the finger, pressing out the crypts, not only of the tonsils but also of the pharynx, will make the subsequent application of Boulton's solution much more effective, because it seems then to get into the crypts.

Dr. M. P. Ravenel, Madison, Wis.: Dr. Jones has brought up an entirely new point of view. Several years ago I recommended that spongy and enlarged tonsils should be massaged. We use the true ivory spatula for this purpose; the finger would do just as well. In cases in which the spray did not act well, massage of the tonsil and use of the spray a second time cleared up the condition in practically every instance, without any trouble. Dr. Jones has brought out another point, namely, the non-contagiousness of the disease in some of these diphtheria-carriers; but what about the condition of the carriers themselves?

Dr. Lawrence and myself have used the staphylococci spray for treatment. It is an excellent method, except in carriers; but we are going to try it next winter early in the case, more exclusively with reference to the treatment of the disease.

Dr. E. F. Otis, Peñuelas, Porto Rico: We are on the right track when we do not treat these tonsils too vigorously with too strong an antiseptic solution. My practice has been to use a very strong alkaline sodium bicarbonate, combined in a normal saline solution, and thus cut away all mucus; and then I use healing oils that are not too strong. I find that this method does not seem to set up an irritating reaction.

Dr. Henry Albert, Iowa City, Iowa: The number of methods that have been discussed emphasizes one of the conclusions that we made; namely, that no one method has as yet proved satisfactory for the proper treatment of the carrier condition.

DISEASES OF PORTO RICO *

ELMER F. OTIS, M.S., M.D.
PEÑUELAS, PORTO RICO

Porto Rico is an interesting island-gem forming an emerald setting of the crescent of the West Indies. The climatic and social conditions are such that the various diseases have no difficulty in making great headway, when permitted to pursue their natural course. It is about the diseases here encountered that I wish to speak.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixty-Fourth Annual Session, held at Minneapolis, June, 1913.

Manson has well said, “If by ‘tropical diseases’ be meant diseases peculiar to the tropics, then half a dozen pages might have sufficed for the description [for, at most, only two or three comparatively unimportant diseases strictly deserve that title]. If, on the other hand [the term] include all diseases occurring in the tropics, then the work would require to cover almost the entire range of medicine.”

TUBERCULOSIS, TYPHOID AND MALARIA

Tuberculosis, typhoid and malaria may justly receive first mention; while rickets, bronchopneumonia, angina pectoris, venereal diseases, tumors, meningitis and a variety of chronic rheumatic affections are not unfrequently found. On account of the fact that the warm climate favors germ growth, varied forms of enteritis take their full toll from among the young people that are born and reared amid tropical surroundings. The death-rate for this disease alone last year in Porto Rico was 41 per ten thousand.

Tuberculosis is a community disease of the thickly settled parts, and is proving to be a most difficult problem to handle in tropical lands. The *Liga Antituberculosis* is working along the general lines of its sister society in America; while the insular government remembers the distressing condition of her “white-plague” victims by periodic appropriations. On account of the rapidly increasing population of the island the number of deaths from tuberculosis per year is numerically on the increase. The death-rate had dropped, however, from 20 to 14 per ten thousand during the fiscal year 1911-1912.

The people of Porto Rico have until recently supposed that when the diagnosis of pulmonary tuberculosis was established, there was absolutely no hope for them. This idea, working in connection with the lack of climatic stimulation and the prevalence of some very unhygienic customs, makes the cure of the patient and the prevention of the spread of tuberculosis even more difficult than in our northern latitudes. The custom of tightly closing all doors and windows, and thereby excluding the night air which is considered so deleterious, brings with it a baneful effect. Very few indeed of the better houses have any provision for ventilation at night time. Those who live in the “shacks’ fare somewhat better from the fact that it is impossible to make these air-tight.

Typhoid fever is practically endemic and, on account of the fact that it is many times confused with paratyphoid and coli bacillosis, reliable statistics are not available. My experience has been that custom strongly opposes the idea that any infectious disease should be diagnosed as it actually exists, and that it should be given the benefit of every possible doubt. Preference is given to a diagnosis that carries with it no unpleasant forebodings.

The general manifestations of malaria seem to be about the same the world over. This, however, is a subject for special study for those of us who are situated in tropical zones. Laboratories are being establised whereby we may study its more uncommon manifestations. There is a virulence which goes with it in the warmer latitudes that is not even to be seen in the north. Those who especially study it think that they can see a possible connection between it and the kala-azar of the East Indies or even the black-water fever of Africa. Malignant malaria is exceedingly common, and the treatment must be heroic, else the patient goes into profound delirium or succumbs to intense toxemia.

TROPICAL ANEMIA

Tropical anemia (uncinariasis or what was first called “lazy-man’s sickness”) is the most interesting to us because of its influence on the health, happiness and prosperity of our people. It was on Porto Rican soil that its identity was first worked out by Ashford. It was here, also, that the enormity of its deleterious effect on human life and efficiency was demonstrated, another of the world’s great economic problems, and thereby solved. Its discovery came at a time when practically every one in Porto Rico was infected, and the hungry *jíbaros* were crying to heaven for relief from their physical disabilities. They were described by Fray Inigo Abad as “having the appearance and color of convalescents.” That was in 1788; and there is little doubt but that the like condition had prevailed since 1530. It was the Medical Corps of the American Army, whose men are ever ready to lay down, if necessary, even life itself, which finally came to the rescue of the Porto Ricans.

The accompanying table gives a few of the results obtained from a special examination of the schoolchildren in our municipality and will be of interest. All classes of children are here represented, and Peñuelas is so situated that almost all physical and climatic conditions are found. Its territory stretches from the coastline to the tops of the mountains. The twelve *barrios* represent almost all industries and social conditions and are therefore typical of the island in general. In spite of the large amount of anemia work that had been done in the place, there was still to be found an average of 38 per cent. of the schoolchildren infected with uncinariasis. Eggs of other parasites, such as *Ascaris, Trichocephalus* and more rare varieties, were found in 72.4 per cent. of the feces examined for the hookworms. I observed that an evident pallor was to be detected in 53.3 per cent.; while the average hemoglobin was 81.5 per cent.

SUNDRY DISEASES

Asthma is frequently found.

Whooping-cough is endemic.

Nervous affections limit themselves to a few—largely on account of the simple life of the majority of the inhabitants; but most of the native women are afflicted with a peculiar form of hysteria in which they must be restrained lest they do themselves bodily injury. It is called *ataque,* and sometimes assumes almost an epileptoid nature.

Among eye affections cataracts are frequently found—especially in those suffering from an intense degree of hookworm infection. A persistent form of conjunctivitis is endemic; however, my expreience has been that it responds readily to medication, when the ordinary hygienic measures are adopted.

Trachoma has never been reported, except in a very few cases in which the infection was caught while sojourning in some other country.

Obstruction of the bowels is commonly encountered. The people in general do not attend to their bowels. Not infrequently the country people report having gone from three to six days without a movement, sometimes twenty days or more have passed. On closer inquiry, however, they usually recollect having had “very slight movements once or twice.” These abnormally long periods are accounted for by them from the fact that often the patient has eaten very little or nothing during his entire illness.

Idiopathic tetanus is quite often reported.

Eruptive fevers, except possibly scarlet fever, are found in Porto Rico, but are usually of a mild character.

Filariasis (elephantiasis), like malaria, seems to confine itself mostly to certain sections of Porto Rico. No satisfactory explanation for this is offered.

The lepers are segregated in a colony on Goat Island within the San Juan harbor. They usually number about forty.

Sprue is more common than was previously supposed, and is being studied by a special committee of the insular medical society. Dr. Bailey K. Ashford's report will appear in due time.

I have not yet encountered in Porto Rico a case of pellagra or dengue. The vital records show none. The former probably exists there.

Beriberi and yaws have been reported, but I have not as yet heard of the diagnosis being confirmed.

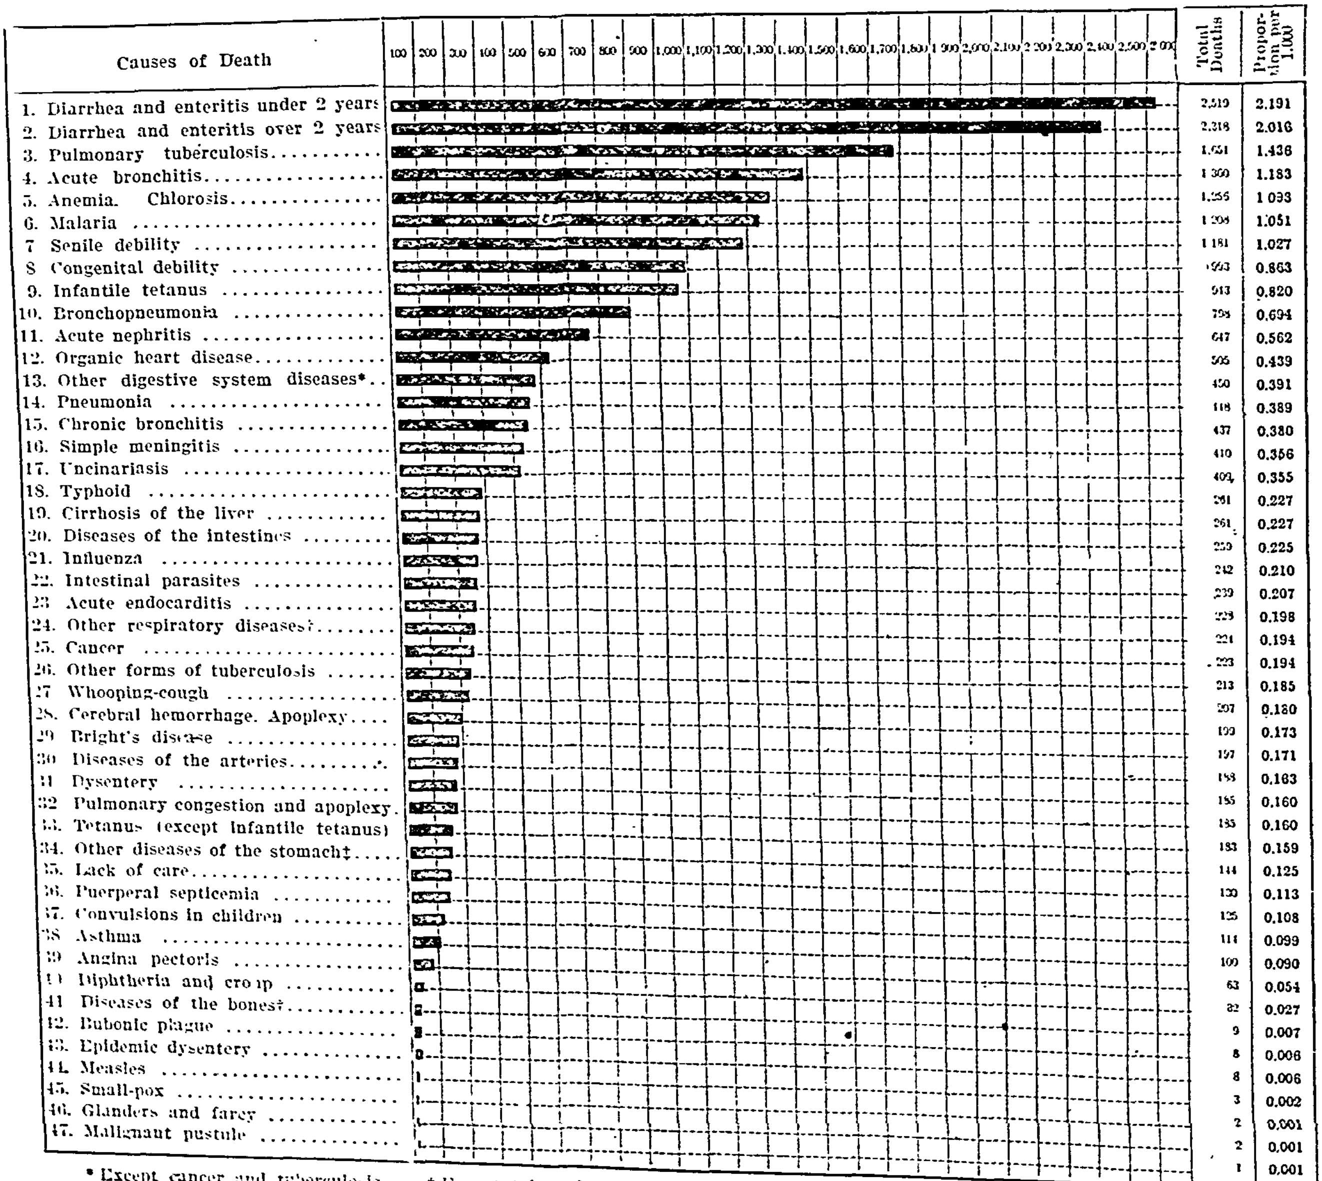
EPIDEMICS

Porto Rico has shared in periodic epidemics with her sister islands for centuries.

Yellow fever is supposed to have originated in the West Indies. No date is given, but it was first reported from Guadaloupe in 1635. Soon afterward it occurred in Barbados, Cuba, Jamaica, Santo Domingo, Martinique and in St. Thomas—forty miles off of our east coast—in 1793. I can find no record of its having become epidemic in Porto Rico, although it is known that occasional cases have been seen there. It is mentioned as having been present in 1783; however it is difficult to obtain accurate data from the Spanish colonial records. Yellow fever is now believed to be a thing of the past in Porto Rico. It has never appeared on the island since the American occupation. During the past year a special campaign has been waged against all kinds of mosquitoes.

Cholera once visited Porto Rico, in 1845, and the experiences are still vivid in the memories of a few of the survivors. The invasion lasted over four months; slaves were decimated by the scourge; it also entered the homes of both rich and poor; the people died "almost in their tracks" and were carted off toward the trenches on the lonely hillsides—sometimes before they were quite dead. One dying woman in a comatose state, who was supposed to have died just as the last rounds for the

CHART OF MORTALITY



Causes of Death	Total Deaths	Proportion per 1,000

* Except cancer and tuberculosis. † Except tuberculosis. ‡ Except cancer.

night were being made, was being transported by a policeman and peon. The fresh air seems to have revived her till she came to herself and desired an explanation as to what was happening. Thereupon, her superstitious "pall-bearers" dropped their charge and fled. She managed to crawl on her hands and knees to a nearby brook and proceeded to alleviate her burning thirst. She shortly recovered.

Another, a boy living in the rear of his father's provision store, was left to his fate while the family were occupied with the "watch" over his dead brothers. He reasoned thus: Although it is considered very dangerous for a cholera patient to take either food or drink, yet it is better to die in comfort with a full stomach than in the miseries of a forced starvation. He improved the opportunity to steal into the store and consume an incredible amount of both bread and water. He had only sufficient strength to crawl from his cot to the store-room, but he was soon up and about and began to insist that his fellow sufferers should also try these measures. Almost all who tried this method survived. The lad is now an old man and takes great pleasure in relating these and many similar experiences which he had when the druggists were the doctors, and customs ruled supreme.

The treatment in vogue at that time was starvation, and deprivation of water and air. A poultice made from a native cactus was applied hot to the abdomen. For this was sometimes substituted the *balleta*, made by sewing together many thicknesses of blanketing and applied as a protection to the trunk.

Small-pox and typhoid have made their periodic visitations—have been at times almost endemic. Thanks to vaccination and the recent introduction of antityphoid injections, these diseases are now found in inverse proportion to the preventive efforts put forth. In the case of typhoid, the campaign against flies and the use of calcium hypochlorite in the drinking-waters has greatly assisted in the results. There are still to be found among the adults many who are pock-marked—an object lesson as to existing conditions in former days. The radical treatment of threatened typhoid epidemics of the last year by the free vaccination of the people gave brilliant results; and I have yet to find a single case in which a person developed the fever after having had the three injections.

Plague was discovered in the Port of San Juan, June 18, 1912, and was immediately recognized. The management and control of the situation by the sanitary department, seconded by the United States War Department, is another brilliant object lesson to the world as to what may be accomplished by concerted effort. There was a total of fifty-five cases with thirty-six deaths. The situation was controlled mainly by the vigorous campaign against rats; and also the use of the antiseptic injections. The last case developed on September 8.

It was demonstrated that the public control of an epidemic need not seriously influence commerce, but serves rather as a safeguard to business by instilling confidence into the minds of the citizens.

Dangers of Short-Circuiting in the Feeding of Infants.—In my private practice I meet wasting infants, who immediately after birth have been submitted to the tender mercies of a wet-nurse in full lactation. If a healthy infant cannot be expected to short-circuit the colostrum period, how much more improbable is it that a delicate and degenerate infant, on whose life, perhaps, much depends, will be able to dispense with simple lessons in digestion and learn to run before it can walk.—Eric Pritchard, in (London) *Clinical Journal.*

THE EFFECTS OF COLLOIDAL COPPER WITH AN ANALYSIS OF THE THERAPEUTIC CRITERIA IN HUMAN CANCER *

RICHARD WEIL, M.D.
NEW YORK

During the past six months, the activities of the research staff of the General Memorial Hospital, devoted under the auspices of the Cornell Medical College to the investigation of malignant disease in human beings, have been in part directed to an analysis of the effects of metals in colloidal solution. In the present communication, the results obtained from a study of colloidal copper will be briefly described. This part of the work is now at an end, and it seems advisable, in view of the very considerable interest in the effects of copper in cases of malignant disease, to contribute to the general discussion of the subject the clinical records which have been collected, and such additional data in this connection as seem to be fairly well established. These records and data have been contributed in part by the clinical service of the hospital, in part by the laboratory departments both of the university and of the hospital, which have severally cooperated in the investigation of this subject. The clinical observations have been made by Drs. Brown, Michailovsky and myself; the chemical data have been contributed by Drs. Benedict and Lewis; the pathologic examinations were made by Dr. Ewing; the photographic and roentgenographic services have been under the direction of Drs. Cole and Holding.

Interest in the therapeutic effects of colloidal solutions of the metals has been very active for about fifteen years. This interest has been largely confined to the effects of these substances in the infectious diseases, owing to the fact that collargol, in particular, has been highly recommended and widely employed in gonorrheal ophthalmia and in general sepsis. During the course of the past year (1912), however, attention was drawn in Germany and France to the fact that the experimental tumors of animals are very strikingly influenced, and in some cases cured, by the intravenous injections of colloidal solutions of the heavy metals and of their compounds. In December, 1912, Leo Loeb[1] and his co-workers published a preliminary article on the effects of colloidal copper in human cancer, containing a detailed report on eight cases. In summarizing their results they state that they "are now able to cause the gradual retrogression of human cancer which until now has withstood various modes of treatment; and, furthermore, that the treatment does not seem to be limited to one kind of cancer, but applicable in the effective treatment of various kinds of cancer." In detail, they observed relief from pain, improvement in the function of diseased areas, general constitutional improvement and gain in weight. The tumors decreased in size, induration lessened or disappeared, granulations sprang up and cicatrization or epidermization played their normal rôle in obliterating or covering the defects produced by the disease. The authors point out, however, that "patients, in whom the growth of metastases is very rapid and extensive, and in whom the cachexia is already very pronounced, cannot yet be benefited by this mode of treatment." In two subsequent papers, of which the latest appeared in May,

[1] Loeb, Leo; McClurg, C. B., and Sweek, W. O.: The Treatment of Human Cancer with Intravenous Injections of Colloidal Copper, Interstate Med. Jour., 1912, xix, 1015.

1913, Loeb[2] confirms his previous report, and adds further records of cases in which colloidal copper has caused a more or less marked diminution in the size of various malignant tumors, citing cases of medullary sarcoma of the humerus, of infiltrating carcinoma of the mouth and cheeks, of multiple carcinoma of the face and neck, of carcinoma of the thyroid, etc.

PREPARATION AND ADMINISTRATION OF COLLOIDAL COPPER

Shortly after the appearance of his first publication, Dr. Loeb was kind enough to give us complete details as to the preparation of the copper solution and as to its mode of administration. Since that time, we have used the method in the treatment of twelve ward patients in the Research Service of the General Memorial Hospital.

In the preparation of the copper, we have followed the method originally employed by Loeb, who states that he followed the method of Bredig.[3] In the solutions prepared in our laboratory the copper was found to be present in amounts averaging 30 mg. per liter (quart). Whether this copper is present as a metal, as an oxid or as a hydroxid has not yet been determined, but one of the latter seems the more likely. When freshly prepared, the solutions give the enzyme reaction with hydrogen peroxid, but only slightly or not at all with benzidin. Within twenty-four hours or less, however, this reaction is markedly diminished or lost. In order to avoid this as well as other secondary changes, we have made a practice of using only fresh solutions.

In the administration of the solution we have followed Loeb's plan, employing exclusively the intravenous route and making injections, so far as possible, on every day of the period of treatment. In this connection arose a problem of theoretical interest and also of some practical importance concerning the behavior of the colloidal solution when in contact with the blood. It has long been known that certain colloidal solutions have a tendency to precipitate each other. When such precipitation occurs, the colloidal state is, of course, altered, and the special properties which characterize substances when in that state are thereby destroyed. In order to determine whether or not such precipitation was likely to occur in the blood-stream on the introduction of colloidal copper, we made a series of test-tube determinations, in which blood-serum and colloidal copper were mixed in varying proportions. The results of these determinations will not here be given in detail. The accompanying table, however, is included in order to illustrate the fact that, in certain proportions, mixtures of human blood-serum and of colloidal copper solutions do produce flocculation. This flocculation is due chiefly, if not entirely, to the copper, and not to the serum. The table confirms the law, deduced by Buxton and his co-workers in Cornell, that colloidal solutions of the heavy metals, when mixed with other colloids in a series of dilutions, present a prozone, in which no flocculation occurs, a midzone of flocculation, and a postzone, in which, again, flocculation is absent.

The table shows the results of mixing equal parts of blood-serum, and of a solution of "colloidal copper," the former diluted with normal salt solution, the latter diluted with distilled water, in the proportions indicated. Controls of copper with salt solution, and of serum with distilled water, in the same proportions as those used in this table, failed to show flocculation.

The table is designed to cover all such combinations of colloidal copper and of blood as might probably result from the intravenous injection of the former. The copper solution might conceivably be introduced in a stream of less volume than that of the blood circulating in the vein, or the reverse of this condition might obtain. The table demonstrates that only in case the blood-serum *is* approximately *one-sixtieth*, or less than that, of the copper solution in volume does flocculation occur. Under the conditions which governed the injections as made by us, it is safe to assume that the blood-stream always dilutes the copper solution in a relatively greater volume than this; the factor of flocculation may therefore be excluded.

VARIOUS DILUTIONS OF RESULTS OF MIXING EQUAL PARTS OF BLOOD-SERUM WITH SOLUTIONS OF COLLOIDAL COPPER

SERUM DILUTIONS

Copper	1:15	1:20	1:25	1:30	1:35	1:40	1:45	1:100	1:500	1:1,000
Undiluted...	—	†	†	†	++	++	++	++	+	+

1/16	—	—	—	—	—	—	—	—	—	—

. The signs used have the *following significations*: +, *immediate* moderate flocculation; ++, immediate pronounced flocculation; †, flocculation after incubation; —, no flocculation.

The fact that the administration of copper in this form has a very marked tendency to produce phlebitis and periphlebitis, and that this tendency becomes accentuated with repeated injections, renders it advisable constantly to vary the site of injection. In a long-continued course of treatment, it becomes necessary to call into requisition all available superficial veins of both upper and lower extremities. On this account obese persons are most unfavorable subjects for treatment and must, in many instances, be considered entirely unsuitable. With the exercise of the utmost precaution, it is frequently impossible to avoid the occurrence of some degree of phlebitis. This may not amount to much more than a slight induration of the veins with some pain. On the other hand, there may be an extreme grade of induration, with thrombosis, severe pain, tense edema, superficial discoloration along the path of the veins and all the concomitants of an intense phlebitis and thrombophlebitis. These lesions, however threatening clinically, have not in any of our cases been associated with more than a very low grade of pyrexia or general malaise. The inference is permissible that they are not septic or infectious in character, but represent merely the result of a chemical irritation of the endothelium. This conclusion is borne out by the inflammatory reaction which almost regularly accompanies the loss of small amounts of the copper solution into the subcutaneous tissue. As might be expected, under this assumption, the local symptoms rapidly subside when treatment is withheld. In no case have we witnessed any clinical indication of embolism, or infarct formation. In some persons the phlebitis has resulted regularly in the obliteration of the affected veins, so that eventually none was left accessible to injection. As a consequence of the impairment to the return circulation, there may be, as in one of our cases, a more or less prolonged condition of low-grade subcutaneous edema.

[2] Loeb, Leo: Summary of Investigations in Tumor Growth Carried out in the Research Department of the Barnard (Free) Skin and Cancer Hospital, St. Louis, Interstate Med. Jour., 1913, xx, p. 298.

[3] Bredig: (Anorganische Fermente, Leipsic, 1901, p. 34) asserts that colloidal copper is one of the metals which cannot be prepared by this method.

The factors which determine the production of this symptom are somewhat elusive. In a series of patients who daily received injections of identically the same solutions, some responded quite characteristically with inflammatory reactions, whereas others did not. Personal idiosyncrasy apparently plays a preponderating rôle in the result. Whether this idiosyncrasy is dependent on certain features of the blood, or of the veins, has not been determined.

GENERAL EFFECTS OF THE INJECTIONS

The constitutional effects of the injections, aside from their effects on the tumors, are of importance. Loeb drew attention to the fact that the earlier injections are followed invariably by a rise of temperature and frequently by a chill. He states that these manifestations decrease in severity with subsequent injections. "The general condition (appetite, strength, complexion) improves." Our own experience does not entirely coincide with these statements. They hold true indeed, of some of our patients. On the other hand, certain of the patients bore very large daily injections—up to 700 c.c. —without any rise of temperature during the earlier period of the treatment, whereas they subsequently reacted violently. In still others, throughout the treatment chills and pyrexia were a constant accompaniment of the injections. These symptoms are not in themselves of serious import, in spite of the fact that they somewhat impair the general health and comfort of the patient. A more disquieting symptom is the nausea, sometimes associated with vomiting, which occasionally occurs and which may materially interfere with the proper nutrition of the patient.

In spite of these undesirable features of the treatment, however, the majority of the patients stand it fairly well over a period of about one month. We have not, indeed, observed that the "general condition improves." On the contrary, our cases have almost without exception shown a slight, though steady, loss of weight, as a rule not exceeding from 5 to 10 pounds. Hemoglobin determinations have shown, as a rule, a steady deterioration of the blood, ranging from 10 to 20 per cent. of the original hemoglobin estimation previous to the use of the injections. These undesirable, though by no means serious, sequelae, seem to us to be attributable to the effects of the copper rather than to the natural progress of the disease and its associated cachexia. Many of our patients have improved perceptibly on the cessation of treatment.

The rather striking pallor of many of these patients cannot be explained on the basis of an increased anemia. It is entirely in excess of the calculable loss of hemoglobin. In view of the generally accepted belief that the colloidal metals injure the wall of the capillaries, a belief which is based on the observed effects in animals, it may possibly be due to a spasm of the superficial vessels. At all events, it is well to realize that the pallor in these cases is no index of their anemia.

A rather striking symptom is the hemoglobinuria which occasionally accompanies an injection. In some patients this is a very exceptional symptom, while in others it has occurred with greater frequency. It is in itself of no great moment, inasmuch as the corresponding degree of destruction of the red blood-cells cannot be great. The hemoglobinuria is never more than slight. In one case, in which it occurred with some frequency, we tried to determine whether the destruction of the red cells was due to the copper or to the distilled water. The injection of distilled water alone, however, on the few occasions on which it was tried, failed to produce the symptom. We are of the opinion, therefore, that the copper exercises some toxic influence on the red blood-cells.

The same toxic effect manifests itself on the kidneys. It is the rule, and not the exception, that the cases under treatment show small amounts of albumin in the urine. If albumin had previously been present, it is likely to be increased in amount. This symptom is in itself of no great clinical importance. The patients give none of the evidences of renal insufficiency, unless occasional headaches be reckoned in this category. It is of importance, however, in conjunction with the hemoglobinuria, as indicating that the copper is not without a destructive effect on the normal tissues and organs of the body.

This impression receives some confirmation from the examination of the organs removed at necropsy from a patient who had been under treatment. The following details have been excerpted from the pathologic report:

> The liver shows capillary congestion. The liver cells show slight granular and fatty degeneration. Their nuclei are greatly increased in number and vary in size, presenting many giant nuclei. The peripheries of the lobules contain a heavy deposit of coarse granular pigment. The right kidney is in a condition of advanced atrophy with interstitial fibrosis. The left is the seat of an intense acute degeneration of tubule cells, many of which are necrotic. The glomeruli show moderate old fibrosis. The tumor is well nourished and actively growing.

In the absence of other etiologic factors, it seems justifiable to attribute these lesions to the action of the copper, especially, in view of the fact that the clinical observations previously described lend definite support to this interpretation.

As regards the excretion of the copper, our analyses show that little, if any, leaves the body in the urine. On the other hand, large amounts are found in the feces. In the absence of a prolonged series of quantitative determinations, it cannot be said that the total amount of the copper introduced by the veins leaves the body by way of the intestines, but it is certain that the major portion can be recovered in the feces.

The distribution of the copper in the body, assuming that a part of it is stored up for a time, is a matter of great interest. As bearing on the problem, we have data derived from one operation and from one necropsy. The case which came to operation was one of sarcoma of the jaw. The patient had been given almost daily injections of the copper solution for a month, during which period he had received, in all, 11½ liters. The injections had been discontinued a few days before the operation. A mass of tumor tissue weighing a little over 60 gm. was examined chemically for copper. Not the slightest reaction, however, could be determined. In view of the fact that the method of analysis employed was found reliable in the recovery of very small amounts[4] of copper when mechanically mixed with organ dèbris, and that, in another case, considerable amounts were obtained from the liver, it is safe to assume that the tumor tissue in this case contained practically no copper.

The necropsy was obtained on a case of embryonal sarcoma, originating in the testicle, and metastasizing to the abdominal lymph-nodes. The patient had received about 3 liters of the copper preparation, and was under treatment until the time of his death. Of the tissues removed at necropsy, the liver, kidney and tumor were submitted to chemical analysis for copper. In a 30-gram and in a 60-gram portion of tumor tissue no trace of copper could be found. The kidney, likewise, was entirely free. In a 90-gram portion of the liver 1.8 mg. of copper were determined, giving a ratio of 20 mg. of copper per kilogram of liver substance. It has long been known that the heavy metals when introduced in considerable quantities into the body, whether by way of the stomach or by any other method, tend to become deposited in the liver. To this rule the intravenous injection of metals in the colloidal state seems to form no exception. In an article published during the current year, Duhamel[5] has shown that when rabbits receive a solution of colloidal iron intravenously, approximately 90 per cent. of the total iron recoverable from the body is found in the liver. In this respect, therefore, the findings in our case are entirely in harmony with those hitherto reported.

---

[4] When 5 mg. of copper, as copper sulphate, were mixed with 60 mg. of tissue, all except a small fraction was recovered.

The absence of copper from the tumors in both of these cases is an observation of some importance. If there were a special affinity between the tumor tissue and the copper—and such an affinity must in all probability be posited if the copper does indeed exercise a specific toxic effect on the tumor—it would be reasonable to expect the presence of copper in some amount in the tumor tissue. Its absence is a priori, a material obstacle to the assumption of any such affinity. There is, indeed, an alternative possibility. It has been suggested that the effects of the colloidal metals in the experimental tumors of animals may be secondary to circulatory disturbances produced by the toxic action of these substances on the endothelia of the capillary muscles. This interpretation is supported by the striking and immediate vascular alterations in such tumors, following the injections. In the case of human tumors, no such vascular concomitants have been observed. At the most, Loeb mentions a passing and slight hyperemia. This possible explanation of the described action of colloidal copper on human tumors cannot, therefore, be entertained. Whatever the explanation may be, the fact remains that no traces of copper could be determined by chemical examination of the tumor tissues examined by us.

CRITERIA OF THERAPEUTIC EFFECTS

In determining the effects of any given mode of treatment on a tumor, a variety of criteria may be relied on. Circulatory changes in the tumor, the relief of pain and the restoration of a secondarily impaired function are certain of the criteria on which stress has been laid by the majority of observers in the past. Important as are these criteria in determining the progress of purely inflammatory processes, it is unquestionable that their value in judging of the effects of therapeutic methods when applied to malignant disease is open to criticism. It is a curious and interesting fact that almost every therapeutic claim made in recent years in connection with cancer has included among its virtues the relief of pain. This is true of vaccination with cancer tissue, of Hodenpyl's method and of many others. Loeb likewise observed it in his cases. In view of this very general effect, not much stress can be laid on this symptom, and it is probably fair to assume that in the great majority of these cases the result is in no small measure psychic. The improvement of function is also largely a subjective phenomenon, and as such requires most careful criticism. Osler relates that he has known a patient with gastric cancer to be relieved of digestive disturbances and to gain 18 pounds in weight as the result simply of the visit of a sanguine consultant who denied the presence of a tumor. Improvement in the ability to chew food, to articulate words or to move a limb are phenomena familiar to those who attempt to treat cases of cancer. The victims of this disease seem to be in a very high degree "suggestible" and impressionable and respond nobly to every therapeutic effort. We have therefore noted, but laid no stress on, this group of criteria.

Circulatory changes in tumors offer an interesting group of clinical symptoms. The observation has often been made, especially in ulcerated new growths, that treatment is associated with swelling, peripheral hyperemia, and an altered character of the discharge. In spite of the fact that there is no reasonable relationship between this congeries of symptoms and the actual cure of the tumor, they generally receive considerable emphasis and are cited as an indication of the specific local action of the agent employed. It may be stated by way of preliminary that these symptoms do, as an actual fact, sometimes accompany the administration of colloidal copper. Indeed, they are described in some detail by Loeb. It is also true, however, that the growth may continue to advance in spite of their presence. It is of some importance to inquire into the mechanism which produces these circulatory changes and into their clinical interpretation. It is a well-known fact that many drugs. when introduced into the body either by the mouth or through the skin, are excreted not only by the normal channels of elimination, such as the kidney or the intestine, but also from such ulcerated surfaces as may be present on the body. This is easily shown to be true, for example, of certain of the anilin dyes, which, when introduced by way of the veins, produce an intense discoloration of the dressings over ulcers. It is likewise true of certain of the metals, such as arsenic. In order to understand the series of events previously enumerated it is therefore only necessary to assume that copper, like many other substances, is excreted from the ulcerated surface of tumors. As an irritant, it will tend to produce hyperemia of the margins of the ulcer, and an increase of the secretions. As an astringent, however, it may produce just the opposite of these effects. Such a result, however striking, is purely accidental, and has no necessary bearing on the growth or destruction of the tumor itself. It constitutes a symptom on which no reliance should be placed.

Excluding from consideration all of these secondary factors, we may conclude that the observation of the size of the tumor itself is the sole criterion on which we can place reliance in judging of the effect of therapeutic measures. This implies, in the first place, that a tumor must be accessible to fairly accurate measurement. Tumors of the uterus, for example, and intra-abdominal growths will only exceptionally fall into this class. In the second place, indirect evidence of a decrease in the size of tumors, such as is afforded by the increased permeability of obstructed passages, as in the case of tumors of the esophagus, pylorus or intestine, must be accepted only with great reserve. Remissions in the obstructive symptoms characteristic of such tumors are a frequent feature of the normal evolution of the clinical history of such growths. The relief of obstruction, however, may be due either to necrosis of the obstructing portions of the tumor, while the remainder continues to grow progressively, or to a relief of the accompanying muscular spasm. Finally, evidence of decrease afforded by the roentgenogram is not sufficiently exact in most cases to afford ground for so important a conclusion as that at present in question.

---

[5] Duhamel: Compt. rend. Soc. de Biol., 1913.

Not only must there be unquestionable evidence, however, of the diminution in size of the tumor, but this diminution must be of a kind not ordinarily attributable to the natural evolution of the tumor. For example, it is stated by Loeb that "a case of multiple carcinoma of the face and neck is markedly improved as a result of the treatment." Without venturing any opinion as to the conditions which obtain in Loeb's case, it is safe to say that multiple tumors offer enormous difficulties in the matter of interpreting therapeutic results. At present we have in the wards of the hospital a patient with multiple metastatic carcinomas of the skin. For several months we have at intervals made accurate measurements of certain of these tumors and have found that some have undergone retrogression, others have entirely disappeared, while still others have continued to grow steadily. In the case which afforded the ascitic fluid used in Hodenpyl's experiments, many of the lymphatic metastases underwent complete retrogression, while the metastatic process in the liver, as was demonstrated at necropsy, increased progressively, and ultimately almost destroyed that organ. Thus, in multiple carcinosis, the retrogression of individual nodules is no indication that therapeutic intervention has produced an improvement.

I shall not delay to emphasize those variations in the size of solid tumors which accompany hemorrhage and its absorption, edematous swelling, necrosis in the depths, and other familiar factors which clinically simulate, or induce, the softening and the reduction that are so often attributed to therapeutic interference. But it is important to draw attention to a similar feature in that type of superficial epithelioma known as rodent ulcer. These new growths not infrequently advance at one point of the periphery, while they recede at another, and thus cicatrization and contracture may simulate a partial recovery. This effect is due in part to alterations not in the growth itself, but in the accompanying ulcerative process. The secretions from the growths, especially if confined under dressings, may have eroded and destroyed the surrounding skin, and it is tempting to interpret a recession of the associated ulcerative disease as an indication of a favorable effect on the new growth. It is unquestionably this aspect of rodent ulcers which plays so generously into the hands of the numerous nostrum venders for this disease.

In brief, the demonstrable reduction in size of a tumor, of a kind not to be attributed to the natural processes of evolution of that tumor or of its associated lesions, is the one essential feature of effective therapeutic intervention.

THERAPEUTIC EFFECTS

The twelve cases treated by us included various types of new growth. There were two cases of cancer of the breast, one of which was very active and extensive; one case of cancer of the rectum; one case of metastatic cancer of the great omentum; two cases of superficial epithelioma, of face and of neck, respectively; four cases of sarcoma, and two cases classed tentatively as endothelioma. Of these cases, four received a thorough and prolonged course of treatment; four received between fifteen and twenty injections; in the remaining four the undesirable sequelae and symptoms of the method itself caused us to discontinue it, in spite of the fact that less than twenty injections had been given. I have chosen from fifteen to twenty injections as defining the meaning of an adequate test of the treatment in any case, in view of the fact that Loeb himself in his second communication states that after this number of injections no further improvement was, as a rule, obtained. In some of our cases, however, over thirty injections were given.

Judged by the therapeutic criteria which have been previously defined, our patients have failed to manifest any improvement under colloidal copper. Every other feature described in the preceding paragraphs we have witnessed—improvement in spirits, in a feeling of strength, in appetite, in function; improvement in the character of the discharge; increased hyperemia; in fact, every symptom of a specific effect, except the crucial condition, namely, a destruction of tumor substance. In the superficial epitheliomas there was so striking a change in the accessory features, notably in the character of the discharge, that careful and unprejudiced observers were positive that the tumor itself had improved; but accurate and regular measurements by means of calipers invariably demonstrated that the tumor itself had remained unaffected, and that there was, at one or more points in the periphery, a progressive advance.

In one case we observed certain apparent effects of the treatment which seem worthy of more detailed description:

Case 1.—*History.*—The patient, aged 45, entered the hospital Dec. 18, 1912. On admission he presented symptoms of extensive involvement of the right lung, and of an intracranial new growth; in addition he had a few large lymph-nodes in the right groin. In another hospital some of the lymph-nodes in the groin had been removed for diagnosis, and had been reported as endotheliomatous, a view in which Dr. Ewing concurred after a study of the sections. The important features of the case were the cerebral symptoms, consisting of severe headache, frequent attacks of projectile vomiting and a double optic atrophy with blindness. These symptoms had been present, with marked variation in intensity, for a period of two years. The patient had been sent in for a decompression, and begged for operation as a means of relief.

Treatment and Course.—From December 24 to January 1, the patient received copper almost daily; from January 24 to February 1, treatment was suspended; it was resumed on February 1 and continued to February 15. During this period he received, in all, over 11.5 liters of colloidal copper solution intravenously. By December 29, the headache had become much less severe, and vomiting had ceased. After the injections were stopped, January 24, there was a return of the symptoms, which again yielded to a second course of injections. The patient was improved in health and spirits during this time, in spite of the fact that he suffered severely from phlebitis. His weight remained constant. He was now discharged at his own request.

March 5, he was readmitted, complaining of severe vomiting, headache and deafness. For five days he received intravenous injections of small amounts of colloidal arsenic, but without improvement. In fact, his condition became complicated by the onset of delusions and delirium. March 17, copper was again administered, and continued daily in large amounts. There was marked improvement in a few days with the disappearance of all cerebral symptoms. The treatment had to be discontinued because of phlebitis. During this second course of treatment the patient received 9 liters. His weight fell from 108 to 102; his hemoglobin dropped from 67 to 62 (by corrected Sahli).

The case is certainly of great interest as indicating an apparent improvement consequent on the use of copper, on three separate occasions. In the absence of direct observation of the intracranial growths, however, judgment as to the mechanism of this effect must be suspended. The accessible new growths, namely, those in the groins, showed no alterations during the treatment. As regards remissions in the cerebral symptoms accompanying tumors, it is well known that they may spontaneously occur and that a person may manifest severe symptoms of intracranial pressure and within a comparatively short time again be free from them. This feature of intracranial tumors has been made the subject of a long and careful clinical analysis by Hawthorn,[6] in a series of studies recently published. It had long ago been recognized by Hughlings Jackson. The cause of these striking changes is, of course, unknown; but they have generaly been ascribed to circulatory variations in and around the tumors. The fact that just such changes may, and do, occur independently of treatment, illustrates the difficulty in interpreting the phenomena from the point of view of the therapeutist. At all events, in no other case did we observe any such striking coincidence between treatment and symptomatic improvement. It is entirely possible, however, that in cases of this type the use of colloidal copper might regularly be productive of favorable results of the character described.

CONCLUSIONS

The preparation described by Loeb as colloidal copper has been administered in twelve cases of malignant disease, in eight of which the treatment was thoroughly carried out. The treatment resulted in most of the cases in the production of mild constitutional effects, such as fever, chills, nausea, some loss in weight, slight reduction of hemoglobin, and occasional albuminuria or hemoglobinuria. Chemical analysis of two tumors from treated patients failed to reveal the presence of copper, while in a liver obtained at necropsy it was present in appreciable quantity. Judged by certain clinical criteria, which have been adopted as a reliable standard of therapeutic effectiveness, the treatment has not appeared to exert a destructive action on the tumor tissue in any of the cases.

CASE-REPORTS

Only such cases as seemed to offer data of special interest have been summarized.

CASE 2.—J. W., man, aged 44, admitted Jan. 23, 1913. Diagnosis: Papillary epithelioma of face. Growth on left side of face of ten years' duration, during which time it had been subjected to various modes of medical and surgical treatment. Growth on admission presented appearance of flat fungating mass, irregularly ulcerated. Purulent discharge, of ill odor; cicatrization, with marked contracture at one angle; sluggish granulations over the base of ulcer. Growth measured 8.5 cm. across, and 4 cm. from above downward. An accurate silhouette made with the help of calipers, and revised at end of each week of treatment.

Eighteen injections, from January 25 to February 17, totaling 7,300 c.c. Ulcer assumed a much more healthy look, granulations improved, discharge lessened and general appearance of growth greatly improved. Measurements made, February 20, showed increase of a little over 1 cm. in each diameter. Extensive and severe periphlebitis and thrombophlebitis. Treatment well borne. No albuminuria, but hemoglobinuria once. Weight fell from 201 to 190; hemoglobin, from 100 to 76 (by Sahli).

Operation: February 27. Radical removal, curettage and fulguration.

CASE 3.—S. L., man, aged 18, admitted Dec. 26, 1912. Diagnosis: Sarcoma of right upper jaw. First appearance of growth dates back seven months. External swelling measures 2½ inches across. No ulceration. General condition of patient excellent.

Treatment: Between December 27 and January 26, twenty-four injections, totaling 11.525 c.c. of copper solution; average almost 500 c.c. During this period measurements of growth were made at frequent intervals. Slow but progressive increase in size of tumor, at a rate which corresponded, so far as could be calculated, approximately with rate of growth previous to treatment. Patient persistently asserted improvement. No loss in weight, or change in general condition.

Operation: On February 4, removal by Dr. Coley. At present, June 1, no sign of recurrence.

Extract from pathologic report: "The section is composed chiefly of medium-sized spindle-cells, with slightly hyperchromatic nuclei and much finely fibrillar intercellular substance. . . . There are many small, irregular, bony and osteoid trabeculae, also many fine globules lying between the cells, which appear to be of osteoid nature. . . . *Diagnosis:* spindle-cell osteogenic sarcoma."

On admission patient had a faint systolic murmur. After operation he failed to recuperate properly. Weight fell from 117 to 100; hemoglobin dropped to 64. In spite of the absence of characteristic symptoms, the diagnosis of malignant endocarditis was made. This has been confirmed at Mount Sinai Hospital by blood-culture findings.

CASE 4.—L. N., man, aged 28, admitted Jan. 15, 1913. Diagnosis: Recurrent sarcoma of chest wall. Four years ago first observed lump under skin of chest. Removed in April, 1908. Recurred in 1909, and again removed. Recurred, and removed for the third time in 1910. Recurred, and treated by Coley's toxins, which proved ineffective. Fourth removal in 1912.

On admission to hospital, patient presented small hard mass, overlying fifth rib on right side. Mass measured 3.9 cm. by 2 cm. It was movable on the deep parts, and not attached to the skin.

From January 17 to February 7 patient received eighteen injections, totaling 6,800 c.c. During this time, loss in weight of 10 pounds. For a few days there appeared to be slight diminution in size of tumor, followed by a period of active and advancing growth; February 8, long diameter measured 4.8 cm.

CASE 5.—J. W., man, aged 54. Diagnosis: Epithelioma of neck. History of twenty years' duration. Ulcerated area measured 8 by 9.5 cm.

Between December 28 and February 1, sixteen injections, totaling 5,900 c.c. Marked phlebitis. Headache, nausea, chills, albuminuria, hemoglobinuria. Progressive improvement in granulations and diminution of discharge. Steady increase in size of growth as measured at intervals by calipers.

CASE 6.—F. A., man, aged 35, admitted March 27, 1913. History extended back almost two years, beginning with enlargement of the cervical lymph-nodes. On admission, chief complaints were difficulty in mastication, pain and paresthesias in the distribution of the second and third divisions of the trigeminus. General nutrition and strength, excellent. On each side of neck, masses of fused lymph-nodes, of moderate size, very hard and immovable on deeper parts. Paralysis of left abducens. Paresis of the temporomasseter and pterygoid groups on left side, and hypesthesia and hypalgesia in distribution of the second and third branches of left fifth.

Examination of nose and accessory sinuses, by Dr. C. G. Coakley, showed left posterior ethmoidal cells and sphenoidal sinus completely filled with hard masses of new growth. This finding confirmed by roentgenoscopy. Patient's weight, 145 pounds. Hemoglobin, 90 per cent. (by corrected Sahli). Urine, normal in every respect. Diagnosis: Primary tumor of nasal sinus, with metastases in cervical lymph-nodes and extension into cranial cavity, involving fifth and sixth nerves at base.

One of smaller lymph-nodes in neck removed for pathologic examination. On this, pathologic report was as follows:

"The node is largely replaced by an alveolar tumor in which there is considerable fibrosis. The cells are arranged in small groups or long anastomosing columns which are usually sharply separated from the connective tissue. Cells are large, polygonal, epithelioid, with pale bodies and multiple nucleoli. They often appear syncytial. There are many large vacuoles, and a great variety of cell inclusions. Diagnosis doubtful; either endothelioma, or epithelioma from transitional stratified epithelium."

From April 6 to May 22 the patient received thirty-five injections, totalling 15,200 c.c. Average, over 430 c.c. for each injection. During treatment no loss in weight or strength.

---

[6] Hawthorne: Studies in Clinical Medicine, 1912, p. 71.

Hemoglobin fell from 90 to 79. Urine regularly showed small amounts of albumin, and occasionally hemoglobin in sufficient amounts to produce distinct discoloration. During first period of treatment patient said that he felt benefited, but toward end asserted that he had become worse. Progressive increase in size of the cervical masses. May 14, ophthalmoscopic examination revealed moderate swelling of both disks, with congestion of temporal halves. On admission the disks had been found normal.

In this case, therefore, there was a failure of the treatment either to hold the growth in check, or to induce any evident degenerative changes in it.

Case 7.—I. R., woman, aged 64, admitted Jan. 3, 1913. Four months previously patient observed lumps in abdomen. Dec. 20, 1912, operated on by Dr. Hartwell at Presbyterian Hospital. He reported an omental tumor; also a small growth on each ovary and one along greater curvature of stomach. "A specimen was taken for examination from the omental tumor, which proved to be carcinoma, the cells being arranged somewhat in tubular form, but the pathologists were unwilling to state the primary origin of the tumor."

On admission the omental tumor was demarcated as accurately as possible, and measurements taken. From January 16 to February 25, patient received twenty injections, totaling 5.225 c.c., and averaging 260 c.c. for each injection. Injections were well borne. Tumor, however, showed a steady increase in size.

In Cases 6 and 7, copper was prepared by electrolysis, as for the other cases, but with a somewhat different technic.

414 East Twenty-Sixth Street.

SKIN RASHES FOLLOWING THE ADMINISTRATION OF ATOPHAN

JOHN PHILLIPS, M.B.
Assistant Professor of Medicine, Western Reserve University Medical Department
CLEVELAND

During the past two years atophan has been used extensively in the treatment of gout, arthritis of different forms and neuritis. Its use has also been recommended in migraine, sciatica, lumbago, iritis, episcleritis, otosclerosis, pyorrhea alveolaris, eczema and urticaria. The purpose of this paper is to call attention to the occurrence of various skin rashes—purpura, urticaria and scarlatiniform eruptions—caused by the administration of atophan as exemplified in the cases reported herewith.

REPORT OF CASES

Case 1.—Man, aged 56, who for twelve years had suffered from the polyarticular form of arthritis deformans, was first given atophan in July, 1911, 7½ grains being administered four times daily. Ten days later a purpuric eruption appeared over the anterior surface of the lower extremities, extending from the knee down to the dorsum of the foot. The lesions were in the form of numerous small petechiae. The medicine was discontinued and in ten days the eruption had entirely disappeared. A week later the medicine was given again in the same dosage and four days later the petechiae again developed, disappearing a few days after the atophan was stopped. Altogether during the past two years. the same experience occurred four times in this patient, that is, every time that this dosage of atophan was taken. It did not occur from smaller dosage.

Case 2.—Man, aged 45, with chronic arthritis of four years' duration, was given 7½ grains of atophan four times daily. Two days after its first administration a severe urticaria developed, affecting the body and extremities and lasting one week. In this patient the atophan was given again one week later, 30 grains of sodium bicarbonate being given with each dose, and the rash reappeared only in very mild form and disappeared again three or four days later without necessitating the stoppage of the drug. Whether or not the sodium bicarbonate was of value in preventing the occurrence of the urticaria is a question that might be raised.

Case 3.—Woman, aged 72, suffering from slight pain in the knees, was given 7½ grains of atophan three times daily. After the second dose numerous urticarial lesions appeared on the body and the medicine was discontinued. It was given again one week later and again the urticaria appeared.

Case 4.—Woman, aged 65, was seen in consultation because of very severe urticaria, affecting the body and extremities, which had persisted for one week. Atophan had been taken in 7½-grain doses three times daily for one month. The urticaria disappeared four days after the drug was stopped. In this case I had no opportunity to find out whether or not it would reappear if the drug was again given.

Case 5.—Woman, aged 53, with chronic arthritis of the left hip, was given 7½ grains of atophan four times daily. The next day a diffuse scarlatiniform eruption appeared over the entire body, extremities and face. This was unaccompanied by fever or sore throat, and disappeared in two days after the drug was stopped. The following week the atophan was again given in the same dose as before, and the next day the scarlatiniform eruption was present, disappearing as before when the drug was discontinued. This scarlatiniform eruption was accompanied by severe itching.

CONCLUSION

These cases show that skin rashes, resembling those following the administration of antipyrin, are not uncommon after atophan has been taken, and that this drug should not be given in the treatment of urticaria as has been advised. Müller[1] has called attention to the occurrence of a scarlatiniform eruption in the case of a girl, aged 23 years. In this patient from 2 to 3 gm. of atophan were given daily in the treatment of arthritis. In the discussion of Müller's paper, Porges mentioned the fact that he had seen urticaria in cases in which atophan had been given.

NERVE-BLOCKING AS A SUBSTITUTE FOR GENERAL ANESTHESIA IN SURGICAL OPERATIONS

M. L. HARRIS, M.D.
CHICAGO

Notwithstanding the inestimable advantages and blessings of general anesthesia as a method of inducing insensibility for surgical purposes, it is not without its serious drawbacks. In addition to the fact that most persons shrink from the idea of losing consciousness, general anesthesia has attached to it not only unpleasant aftereffects, such as nausea, vomiting, headache, pulmonary irritation, pneumonia, suppression of urine, etc., but also the occasional, unavoidable sudden death.

It has long been the hope of surgeons and experimenters that some method of inducing insensibility to pain might be discovered which would be free from all the objectionable features of practically all the present known methods of inducing general anesthesia, and this hope seems now to be realized. Physical pain is the perception of afferent impulses received from that portion of the body which is the subject of injury. If no impulses reach the brain from the injured part, no pain is felt. The impulses or stimuli are transmitted from the periphery to the centers exclusively by the sensory nerves. If the power of the nerves to transmit these impulses be temporarily suspended by any means, any amount of injury may be inflicted to the parts supplied by the nerves whose function is suspended without the patient being conscious of such injury. The newer method of inducing anesthesia consists in suspending temporarily the power of the nerves to transmit afferent impulses and is called nerve-blocking. Nerve-blocking is produced by infiltrating a small portion of the nerve somewhere in its course between the periphery and the spinal cord with some substance which temporarily suspends its action. Not only does nerve-blocking prevent absolutely all pain from the region blocked, but it likewise prevents completely all general shock from any injury received to the parts blocked.

---

[1] Müller: Nebenwirkung des Atophans, Gesellsch. f. inn. Med. u. Kinderh., Feb. 13, 1913; abstr., Therap. Monatsh., xxvii, June, 1913, p. 468.

Shock may be defined as a condition in which there has been a sudden or rapid discharge of the potential energy of the nerve-centers, the result of afferent impulses or stimula, due to peripheral injury. Without afferent stimuli, shock cannot be induced. By blocking the nerve to the passage of afferent stimuli, shock as an element in peripheral injury is entirely and completely eliminated. A leg for instance, the nerves from which have been blocked, may be crushed without the slightest evidence of pain or shock to the patient. As a surgical operation in a sense is simply an injury to some part of the body, it necessarily follows from what has preceded that a surgical operation performed on any portion of the body the nerves from which have been blocked will be unaccompanied by either pain or shock. During general anesthesia no pain is perceived, but shock is always induced, the anesthetic notwithstanding. Every surgeon knows that shock is always present to a greater or less degree, in all operations performed under general anesthesia, the degree of shock depending on the amount of injury done and the duration of the operation, but it remained for Crile to demonstrate by experiment that even under profound general anesthesia afferent impulses are still received by the nerve-centers and that the potential energy of these centers is discharged by those impulses and thus shock results. Of course the shock is by no means so great as without the anesthetic, but it is an unavoidable element in every operation performed under general anesthesia, while under complete nerve-blocking, shock is absolutely and entirely eliminated. It may seem almost incredible to many that the flesh can be cut and the bone sawed with the patient in full consciousness, yet perceiving no pain and suffering no shock; but such is a fact. That consciousness is retained in these operations may seem to many to be an objection to the method, but I think that in the majority of the cases it is a distinct advantage. There is no unpleasant psychic effect, as might be supposed, and even in nervous persons and children I have found no trouble in this respect. In addition to the fear of loss of consciousness the horror which many persons have of an operation is based on the fear of pain. If unconsciousness and all pain and shock be eliminated the operation has been robbed completely of all its terrors; and this is exactly what nerve-blocking does.

Some months ago I began doing operations under nerve-blocking. The method proved so satisfactory in every way that its use was rapidly extended, until at present I do almost all of my operations by this method, and the use of a general anesthetic has become a rare exception. During this time I have operated on carcinomas of the face; tubercular glands of the neck; goiters and other tumors of the neck; carbuncles of the back of the neck; numerous affections of the extremities, including the plating of fractures; tumors of the abdominal wall; hernias; appendectomies, both acute and interval; gastrostomies; gastro-enterostomies; acute intestinal obstruction, due to volvulus and peritoneal bands; ovarian tumors; uterine fibroids; suprapubic and perineal prostatectomies; movable kidney; stones in the ureter and bladder; affections of the rectum, perineum and vagina, etc. It is unnecessary to give in detail all of these operations, but a few may be mentioned briefly to show what can be accomplished and how little effect operations done under nerve-blocking have on the patient.

REPORT OF CASES

CASE 1.—Mrs. R., aged 42, had, I think, the largest goiter that I ever attempted to remove. It was composed of three distinct masses, that on the right side extending so high as to displace the lobe of the ear; that in the midline extending from the chin to the sternum, while that on the left side extended considerably below the upper end of the sternum. It compressed the trachea so that she had great trouble in breathing. The operation was a difficult one and took nearly an hour and a half to complete. The patient talked to me repeatedly during the operation and expressed herself as suffering no pain. She left the table with a pulse of 88; it was usually 80 during the several days she was in the hospital before the operation. At the end of the operation she asked for a drink of water, which was given her. The next day she requested to be allowed to sit up, and made a rapid recovery.

CASE 2.—Miss G., aged 12, had been suffering for some time with a large bunch of tuberculous lymph-nodes of the neck which had broken down and had been partially operated on by some one before. The dissection was a difficult one and required the removal of a portion of the jugular vein. It was done by blocking the cervical plexus and not a particle of a general anesthetic was given. Twice during the operation she was asked if she would like to be put to sleep, but she said "No, go ahead and finish the operation." It is very evident that she suffered no pain, for being but a child of 12 she could not have controlled herself had she had any great pain. She had had ether for the first operation, which was small compared to this one, but she said she would not think of taking ether again for an operation.

CASE 3.—Mr. K., aged 56, had marked obstruction of the pylorus; fully 50 per cent. of a barium meal was still found in the stomach after twenty-four hours, as shown by the Roentgen ray. He vomited daily and had lost many pounds in weight. A diagnosis of carcinoma of the stomach was made. The abdomen was opened under nerve-blocking. No mass was found in the stomach or the pylorus, and there were no glandular metastases. The stomach was opened and explored thoroughly. The stenosis of the pylorus which was very marked was evidently benign in its origin. The stomach was closed and the usual posterior gastroenterostomy done. When the patient went to the operating-room his pulse was 72, and on his return from the operating-room it was 74. He expressed himself as scarcely knowing that he had been operated on.

CASE 4.—Mrs. M. had a large multilocular ovarian cyst, the size of an eight months' pregnancy. Operation performed under nerve-blocking. Extensive adhesions were found, fixing the tumor to the left parietal wall. The patient conversed during the operation and the only thing she said she felt was a peculiar drawing sensation in the abdomen when the tumor was turned out. She left the operating-room smiling and talking pleasantly with the nurse. She wanted to get up the next day.

CASE 5.—Mr. G. had a small sharp-angled stone lodged in the lower end of the left ureter, which was giving him a great deal of trouble. The nerves supplying the left lower portion of the trunk and pelvis were blocked. The usual extraperitoneal incision for exposing the lower ureter was made. The ureter was followed down as far as possible, but the stone could not be felt. The peritoneum was opened and the ureter palpated down to the bladder, but the stone still escaped detection. The peritoneum was closed and the incision carried downward and inward until the fundus of the bladder could be reached. The ureter was opened at the brim of the pelvis and a long probe introduced. The bladder was opened so that the finger could be inserted, and the stone could now be felt between the end of the probe in the ureter and the finger in the bladder. After some manipulation the stone was finally pushed on into the bladder and removed. The operation was long and tedious. The patient's pulse at the end of the operation was 86, during the several days that he was in the hospital before the operation his pulse had ranged from 76 to 80.

These cases are sufficient to show what can be done under nerve-blocking and to show the entire absence of shock even in very severe and prolonged operations. This absence of shock is very remarkable indeed. Not a single patient on whom I have operated under nerve-blocking has expressed a regret at not having taken a general anesthetic, but all have been delighted with the result and every one has stated that were he obliged to submit to another operation, he would not think of taking a general anesthetic.

The technic of the method is quite simple. The nerves supplying the part are infiltrated for a short distance somewhere between the part to be operated on and the spinal cord. The method is entirely different from the old intraspinal anesthesia. There are several substances which will block nerves in this way, among which may be mentioned cocain, the various forms of eucain, stovain, novocain, quinin and urea hydrochlorid, etc. Some of these are so toxic as to be unsuited to the purpose. The substances which I have used are novocain and quinin and urea hydrochlorid, the former in solution 0.0025 : 0.01 with the latter 0.0025 : 0.005 solution. These substances are but very slightly toxic and may be used to the extent of several hundred cubic centimeters, depending on the strength of the solution. The exact points of injection naturally depend on the region to be blocked. The idea is to block all of the nerves supplying the part to be operated on. One must have an accurate knowledge of anatomy and some experience in order to reach the right points successfully. After the injection, it requires from five to thirty minutes for the anesthesia to become complete, depending on the place of injection and the size of the nerve to be infiltrated. As the method requires some skill and practice to secure perfect results, we see opened up here a new field for the expert anesthetist or nerve-blocker, one who in a busy clinic can have the patient ready for the operator at the right time. The method is so simple, so successful, and possesses so many advantages that it opens up a new era in surgery and I believe marks the passing of the general anesthetic in surgical operations. Fuller details regarding technic and points of injection will be enlarged on in a future paper.

32 North State Street.

"What I Have Said, I Have Said," or The Folly of Always Adhering to One's Original Diagnosis.—Moynihan said that some surgeons seemed to think that it was a humiliation for them to open an abdomen, after making a diagnosis on reasonable grounds, and not to discover the particular condition which they had supposed to be present. He had himself no compunction in throwing his diagnosis aside as soon as it was found to be wrong and going in search of something else. . . . And if any precedent was required it could be found in the example of Saul, who went in search of his father's asses and found a kingdom. The one thing against which he could not inveigh too strongly and too constantly was that of making the diagnosis, not verifying it at the operation, but proceeding, nevertheless, to the performance of the operation originally planned.—(London) *Clinical Journal.*

MANGANESE TOXICOSIS

R. VON JAKSCH, M.D.
Clinical Professor, University of Prague
PRAGUE, AUSTRIA

From the paper of L. Casamajor[1] I learn that in the mines and factories of America cases of manganese toxicosis occur not infrequently; cases such as have been described, first, in 1823, by Couper; in 1901 by myself[2] and Embden and then by Friedel. That induces me to communicate briefly to my American colleagues my clinical observations in connection with that interesting and well-known morbid state.

I think that the nervous affections among workmen in factories who are occupied with the production of potassium permanganate and among workmen in mills who are working in an atmosphere full of dust of manganates and in workmen in manganese mills, are produced through the inspiration of dust containing manganates.

I reach that conclusion from the circumstance that in the factory from which I gathered my observations, after the spread of dust had been prevented, the workmen were thenceforth free from such affections.

The symptoms are the following: In the beginning of the disease there occur convulsive laughter, weeping and mental alterations of every kind. In the progress of the disease comes a period during which the patients show the symptoms of retropulsion and a complex of symptoms which resembles the Romberg symptom, but differs somewhat from it. At this time one finds spastic gait, increase of the tendon reflexes, no alimentary glycosuria. Babinski's reflex occurs by plantar flexion in the physiologic way. One observes, further, increased salivation, mask-like expression of the face and monotonous voice. Later on the mental symptoms recede and one observes a gait which is characterized by the patient's stepping forth with the metatarsophalangeal joint first. The prognosis as to life is good, as to recovery bad. The affections may show a standstill; the symptom of retropulsion and the pseudo-Romberg symptom may vanish, but in well-developed cases the gait I here describe persists so that complete restoration is scarcely probable. But I do not deny that slight affections occur which may be cured without persisting gait-troubles after the ceasing of the symptoms described above.

The diagnosis is easily made from the circumstance that people showing those symptoms are usually found occupied in the production of potassium permanganate; in manganese mills and in mines containing ores rich in manganous oxid.

Experiments with dogs, in order to produce the disease by allowing them to inspire a dust full of manganates through a period of months had no results. The treatment consists in the use of cold-water cures, physical exercises, use of the walking-chair (described by me), use of electricity in the form of galvanization, faradization and high-frequency.

I desire to mention that I observed a case from such a factory which showed similar symptoms, and, besides, a marked reduction of the white and red fields of vision, and yet, after a very short time, the patient recovered. Therefore, I think that we must recognize in this case—

the patient being a very intelligent workman who watched with terror the disease of his fellows—a case of manganophobia.

Finally, I mention that I could not succeed in discovering manganese compounds in the urine even after examining great amounts of urine from many such patients together. Nor could I find any evidence of this in such cases in the post-mortem examination.

REPORT OF A CASE OF MONOCULAR PARALYSIS OF THE ACCOMMODATION DUE TO LUES

JESSE WRIGHT DOWNEY, JR., M.D.
Surgeon to the Baltimore Eye, Ear and Throat Hospital; Ophthalmologist to the Home of the Friendless
BALTIMORE

The following case is thought to be worthy of recording, not only because of the comparative rarity of the condition, but also with the belief that the lesion was probably prodromal of a more serious central nervous system involvement, which has probably been prevented, and certainly has been stayed by prompt antisyphilitic treatment.

Mr. N. S. D. was referred to me Jan. 28, 1913, by Dr. Thomas R. Boggs, through whose courtesy I am now at liberty to report the case. The patient had had syphilis five years previously and at that time had been under treatment for eighteen months; since then his general health had been excellent. On January 12, following a long stretch of book work, to which he was unaccustomed, he had felt a fluttering sensation in the left eye and a day or so later had noticed that the vision of that eye was quite blurred for reading. The condition continuing, he came to Baltimore for an examination. Following a general examination by Dr. Boggs, which disclosed nothing of importance except a positive Wassermann reaction, I found the following eye condition:

Right Eye: Pupil normal in size, responding normally to light. Fundus normal. Vision 20/20. Punctum proximum, 18 cm.

Left Eye: Pupil partially dilated, responding very sluggishly to light. Fundus normal. Vision 20/30 (with + .50 sp. ⌒ + .25 cy. ax. 90° = 20/20). A plus 4 D. sp. lens was required to bring the punctum proximum to 18 cm. Field normal for white, blue and red.

Consensual reaction from right to left, very slight. From left to right, normal. The right pupil responded to accommodation, the left did not. Both pupils responded to convergence.

The condition was clearly a paralysis of the accommodation of the left eye with probably a slight involvement of the sphincter pupillae. Wilder[1] reports two similar cases and quotes Hosch's records of five cases and Alexander's report of twenty-eight, all luetic. The lesion is probably nuclear and lies between the sphincter nucleus and the point where the fibers from the ciliary nucleus joins the pupillary light reflex bundle.

Under the direction of Dr. Boggs, the patient was given an intravenous injection of salvarsan and placed under appropriate treatment.

Feb. 23, 1913, the patient reported by letter as follows:

> Physically I am feeling fine and the vision of the left eye is much better. I can now read newspaper print with that eye at short range, though there is still some haziness. The pupil is somewhat larger than that of the right eye, but it is hardly noticeable.

July 9, I had the privilege of again examining Mr. D. and found that the pupils were equal, the accommodation of the left eye had completely recovered its normal functioning and the reflexes were normal. A Wassermann test gave a negative reaction.

506 Cathedral Street.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS ARE ASKED FOR TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK "NEW AND NONOFFICIAL REMEDIES."

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT, SO FAR AS KNOWN, IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

GLUTEN FOOD A, Barker's.—Barker's gluten food A is gluten flour prepared from wheat and contains not more than 4 per cent. of carbohydrates and 87 per cent. of protein.

Barker's gluten food A is made from wheat flour by elutriation. It is a granular powder practically without odor or taste and is insoluble in water.

Actions and Uses.—Barker's gluten food A is indicated when a diet practically free from carbohydrates is desired, especially in most forms of diabetes. It can be taken uncooked or made into muffins.

The nutritive value of 500 gm. of Barker's gluten food A corresponds to 1850 calories, of which 1740 are due to protein, 80 to carbohydrates and 30 to fat. (Rep. Conn. Agr. Exp. Sta., 1913, Part 1, p. 18.)

Manufactured by Herman Barker, Somerville, Mass. No U. S. patent or trademark.

GLUTEN FOOD B, Barker's.—Barker's gluten food B is gluten flour prepared from wheat and contains not more than 7 per cent. of carbohydrates and 85 per cent. of protein.

Barker's gluten food B is made from wheat flour by elutriation. It is a granular powder practically without odor or taste and is insoluble in water.

Actions and Uses.—Barker's gluten food B is indicated when a diet practically free from carbohydrates is desired, especially in most forms of diabetes. It can be taken uncooked or made into muffins.

The nutritive value of 500 gm. of Barker's gluten food B corresponds to 1870 calories, of which 1700 are due to protein, 140 to carbohydrates and 30 to fat. (Rep. Conn. Agr. Exp. Sta., 1913, Part 1, p. 18.)

Manufactured by Herman Barker, Somerville, Mass. No. U. S. patent or trademark.

GLUTEN FOOD C, Barker's.—Barker's gluten food C is gluten flour prepared from wheat and contains not more than 12 per cent. of carbohydrates and 83 per cent. of protein.

Barker's gluten food C is made from wheat flour by elutriation. It is a granular powder practically without odor or taste and is insoluble in water.

Actions and Uses.—Barker's gluten food C is indicated when a diet practically free from carbohydrates is desired, especially in most forms of diabetes. It can be taken uncooked or made into muffins.

The nutritive value of 500 gm. of Barker's gluten food C corresponds to 1880 calories, of which 1680 are due to protein, 170 to carbohydrates and 30 to fat. (Rep. Conn. Agr. Exp. Sta., 1913, Part 1, p. 18.)

Manufactured by Herman Barker, Somerville, Mass. No. U. S. patent or trademark.

THE GASTRIC MOVEMENTS IN HUNGER

The detailed experimental analysis to which the physiology of hunger has been subjected by Cannon of Harvard and Carlson of Chicago has revealed a large number of facts of immediate import made doubly valuable because in many instances they were ascertained or controlled on man. It is now clear that the sensation of hunger, or the "hunger pang," is due to periodic contractions of the empty stomach rather than to some less definite temporary nutritive condition or state of the blood. We have already commented[1] on the further fact that the hunger contractions can be controlled. All stimuli that act on the end-organs of taste and general sensation in the mouth cavity, as for example in the case of chewing palatable food during hunger, reflexly inhibit these gastric movements.

In searching for the actual cause of the hunger contractions of the empty stomach, the stimulus for which might be conceived to be some condition of the blood or sought in the vagus tone or in a primary automaticity of the gastric neuromuscular mechanism, Carlson[2] has discovered further inhibitory phenomena of not a little interest. Water, at body temperature or nearly ice-cold, acting directly on the gastric mucosa inhibits the tonus and the hunger contractions of the stomach. All acids, or liquids containing acids, including normal human gastric juice, check these movements of the empty stomach. The duration of the acid inhibition is said to be determined in all probability by three factors: (1) passing of the acid into the duodenum, (2) fixation and neutralization of the acid by the mucous gastric secretion, and (3) neutralization by bile and intestinal juice which at times pass into the stomach through the dilated pylorus. The degree of inhibition produced by normal gastric juice is the same as that caused by an equal quantity of hydrochloric acid of a concentration equal to the free acidity of the gastric juice. It would thus seem that the hydrochloric acid in the gastric juice constitutes the stimulus that leads to the inhibition.

These striking features at once bring to mind what seems to be a contradictory fact, namely, that such acid inhibitions do not become manifest during the gastric movements in normal digestion, although the stomach is frequently filled at such periods with strongly acid secretion. Indeed, there is reason to believe that during digestion a certain degree of free acidity actually facilitates the digestive movements. Carlson has pointed out that it does not follow, because acid in the stomach inhibits the hunger contractions but not the digestion contractions, that the mechanisms involved in these two types of gastric activity are necessarily different, for the digestive movements involve primarily the pyloric end, while the hunger movements involve the fundus of the stomach. It is possible that acid stimulation of the nerve endings in the gastric mucosa leads reflexly to inhibition of the fundus and peristalsis of the pyloric region of the stomach.

Trials with alkalies make it clear that alkalinity has the same effect on the hunger contractions as acidity only to a lesser degree. Most striking, however, is the unexpected, yet undeniable outcome of the investigation regarding the effect of alcoholic beverages on the hunger contractions of the stomach. From the wide-spread belief that a glass of wine, beer or other alcoholic fluid taken before meals increases the appetite (and perhaps the hunger), and from the authentic statements that a drink of wine seems to initiate the sensation of hunger, one would expect to find that the tonus and gastric contractions which give rise to it are distinctly augmented by these beverages. The results proved to be the very opposite. Wine, beer, brandy and pure alcohol introduced directly into the empty stomach inhibit the hunger contractions of the organ instead of increasing them. Indeed, they cause inhibition only. As a possible explanation for this paradox we may cite some of Carlson's comments regarding the failure of alcoholic beverages either to initiate or to increase hunger. He says that since most alcoholic beverages stimulate the end-organs of taste and smell as well as those of general sensibility in the mouth cavity and in the esophagus, it is possible that this stimulation in some way augments or initiates appetite for food. If this is true we have the singular phenomenon of alcoholic beverages augmenting appetite and inhibiting hunger at the same time. There can be little doubt that cerebral states as modified by training and habit are also a factor in the apparent action of alcoholic beverages on appetite. It is certain that a person's first taste of them does not focus his attention on food and eating. If alcoholic beverages in the stomach caused as marked inhibition of the stomach movements in digestion as they do in the case of the stomach movements in hunger, even moderate drinking with meals would speedily lead to acute indigestion. Inasmuch as this is not the case, the assumption seems warranted that alcoholic beverages affect the mechanisms of the two types of movement differently.

[1] The Stomach in Hunger, Editorial, The Journal A. M. A., Feb. 8, 1913, p. 448.

[2] Carlson, A. J.: The Influence of Stimulation of the Gastric Mucosa on the Contractions of the Empty Stomach (Hunger Contractions) in Man, Am. Jour. Physiol., 1913, xxxii, 245.

As a corollary to the fact that acids as well as normal gastric juice inhibit the hunger contractions of the stomach, it may be supposed that persons having gastric hypersecretion or hyperchlorhydria experience little or no true pangs of hunger of gastric origin. We are not familiar with clinical observations on this point. It is by no means impossible, however, that in cases of prolonged hypersecretion the inhibitory influence of the acid on the overstimulated mucosa is gradually abolished so that a readjustment and restitution of hunger phenomena may occur even in such cases.

THE TRUTH ABOUT OZONE

The necessity for taking with critical doubt statements and claims made by those who have for sale something of claimed prophylactic or therapeutic value, is again demonstrated by the articles elsewhere in this issue on ozone. By the manufacturers of ozonizing machines ozone has been vaunted as a valuable remedy in many diseases, as an effective room disinfectant, as a "purifier of the air" and a restorer of exhausted human vitality. How misleading and even mischievous such claims are is shown by the detailed investigation and discussion of the ozone question by Jordan and Carlson. Ozone is a *toxic gas. So far as the evidence goes ozone* produces no reaction in the human organism or in the lower animals that can be regarded as in any degree beneficial either in combating or warding off infectious disease. On the contrary, all appreciable physiologic changes produced by the inhalation of ozone are distinctly of an injurious and weakening character.

The claims made for ozone as an aid to practical room ventilation would be farcical if they were not altogether deplorable. So far as the destruction of bacteria is concerned ozone is of no practical importance. The experiments of Jordan and Carlson are independently confirmed by the work of Sawyer, Beckwith and Skolfield, also published in this issue of THE JOURNAL. The results of all scientific investigation of this subject, in fact, are in substantial accord. An amount of ozone that can be tolerated in the air of a room by human beings has no bactericidal action. Even much larger amounts are relatively inactive and feeble compared with other well-known gaseous disinfectants.

As a "deodorizer" ozone is of dubious value. While in very great concentrations ozone seems capable of oxidizing some odorous substances, it is without effect on others, as for example, ammonia vapor. The "deodorizing" effect of ozone is, however, largely a masking effect due in part to the intensive odor of ozone itself (very disagreeable to many persons) and in part perhaps to fatigue or anesthesia of the olfactory epithelium. We agree with the authors cited in the statement that "it is probable that the injury to the respiratory tract by ozone in sufficient concentration to act as an effective mask is of greater moment than the deleterious action of most odors." Why try to mask or destroy odors when they are simply a danger-signal that ought to be heeded?

The claim that the operation of an ozonizing machine in a room makes the occupants "feel better" and display more energy is beside the point. So do other irritants. So does a cocktail—temporarily. Any device for whipping up a fagged brain, whether inhalation of a poisonous gas or something else, will seem to unobservant people to be of benefit. At how great a cost their temporary burst of energy or feeling of well-being may be secured is well known. It is quite possible, furthermore, that some of the effects attributed to ozonizers in "freshening" the air are nothing but the results of air currents which, as is well known, favor heat regulation by the body, and differ in no wise from the results obtainable by a simple electric fan. There is in fact no evidence that can reasonably lead us to add a poisonous gas, such as ozone is, to the air of rooms or to administer it to a patient.

One aspect of the matter is the responsibility of reputable and honorable manufacturers for the exploitation of cures and remedies. We do not for a moment question the good faith of many who have urged the use of ozonizers or their belief in the efficacy of their wares. It is easy, however, for those whose business it is to convince others of the worth of their merchandise to begin by convincing themselves with insufficient evidence. To all such we would commend for consideration that little fable with which the clear-thinking and plain-spoken young physicist Clifford prefaces a discussion of "The Duty of Inquiry." "A shipowner was about to send to sea an emigrant ship. He knew that she was old, and not over-well built at the first; that she had seen many seas and climes, and often had needed repairs. Doubts had been suggested to him that possibly she was not seaworthy. These doubts preyed on his mind and made him unhappy; he thought that perhaps he ought to have her thoroughly overhauled and refitted, even though this should put him to great expense. Before the ship sailed, however, he succeeded in overcoming these melancholy reflections. He said to himself that she had gone safely through so many voyages and weathered so many storms that it was idle to suppose she would not come safely home from this trip also. He would put his trust in Providence, which could hardly fail to protect all these unhappy families that were leaving their fatherland to seek for better times elsewhere. He would dismiss from his mind all ungenerous suspicions about the honesty of builders and contractors. In such ways he acquired a sincere and comfortable conviction that his vessel was thoroughly safe and seaworthy; he watched her departure with a light heart, and benevolent wishes for the success of the exiles in their strange new home that was to be; and he got his insurance-money when she went down in mid-ocean and told no tales.

"What shall we say of him? Surely this: that he was verily guilty of the death of those men. It is admitted that he did sincerely believe in the soundness of his ship; but the sincerity of his conviction can in no wise help him, because *he had no right to believe on such evidence as was before him*. He had acquired his belief, not by honestly earning it in patient investigation, but by stifling his doubts. And although in the end he may have felt so sure about it that he could not think otherwise, yet inasmuch as he had knowingly and willingly worked himself into that frame of mind, he must be held responsible for it."

HEALTH AND FINANCE

It has been said that this is an age which places an ever-increasing emphasis on the relation of good health to individual hygiene, to social effectiveness, to general prosperity. Other things being equal, the race is to the community whose children thrive and whose workers keep well. As relates to the community, at least, human health is a purchasable commodity, as has been repeatedly demonstrated. Cuba, Panama and the Philippines afford examples, each, however, under control as to forces and expenditures differing from those of the ordinary community, but confronting conditions infinitely more difficult. And even at that the expenditure has not been relatively great. The average community is in far better position to purchase health.

New York City, with its advanced health ordinances and comparatively liberal supply of money to carry them out, is a striking example of what an urban community can do in the way of a radical reduction in infant mortality and in the general death-rate. Yakima County, Washington, is another example showing the result of systematic health work and liberal expenditure in a rural district. In twelve months under a full-time health officer, with a well-equipped laboratory and a corps of visiting nurses and sanitary inspectors, the death-rate in the county from typhoid fever was reduced from 128 per hundred thousand to sixteen, and the deaths from all causes fell from 538 in 1911 to 393 in 1912. Other instances of like effective work might be cited.

As the mayor of Colorado Springs said recently in welcoming the delegates to the meeting of the American Public Health Association, the problems of public health are even more vital than those of individual health. Appreciation of this fact comes slowly. Money to purchase public health is given grudgingly by those in charge of the public purse. For instance, St. Louis, the fourth city in the United States in both population and manufactures, spends annually only $100,000 on its health department, whereas it spends $2,000,000 annually on its police department, twenty times the amount spent for the promotion of public health. It might be added that a large portion of this expenditure for police protection —and this applies to all cities—is made necessary by the tolerance of the saloon and the brothel, two important direct sources of ill health (as well as crime) which add to the burden of the health department with its inadequate appropriation. Larger appropriations for health purposes will only follow the creation of public sentiment demanding them, and in accomplishing this the newspapers must perhaps play the chief rôle. The St. Louis *Republic*, recognizing this, has applied itself to the creation of a public demand for better support of the health department of St. Louis, and will present a plan for making that city the healthiest in the United States. At present the death-rate in that city is considerably less than that of other large cities in the same latitude, and almost as low as that of Cleveland, New York and San Francisco, cities more favorably located geographically and climatically; but it is believed that it can be made still less. This commendable object will require not only increased appropriations for the health department, but the sustained cooperation of all the citizens, and it is this cooperation which, with an intelligent grasp of the requirements, the *Republic* has begun a campaign to secure.

The newspapers and the citizens of every community should awake to the fact that community health is a first principle of effective local government, and should adopt for their slogan, Public Health Is a Purchasable Commodity.

THE NUTRITION OF THE POOR

These are days in which problems of economy in living are forcing themselves on the attention of the public mind. The rise of prices has intruded itself into the conduct of the household and compelled a readjustment in some cases in the distribution of income among the various channels of expenditure. Whatever else may happen, it is fundamentally necessary that certain indispensable requisites of clothing, shelter and food be provided if the individual is to be maintained in a state of physiologic equilibrium and economic efficiency. In the so-called "better classes" the appropriations to such purposes can be adjusted without serious difficulties; but as we descend in the scale of available income a border-line is reached at which the barest necessities of life may not always be suitably provided. It is to this stratum of society that the attention of social workers and students of nutrition alike must be directed if reforms are demanded and deserve to be established.

So much has been written about the influence of diet on the physical conditions of the individual, and particularly on growing children who become the workers of the next generation, that most statements in this field appear like trite truisms. There are statistics to indicate that when the weight of children is much below the average for their age, almost without exception their diet is inadequate. This is a single illustration of the way in which the physiologic, and consequently the economic, welfare of the individual among the poorer classes becomes seriously menaced in the struggle for existence. Inasmuch as food is the fuel—the source of energy—of the human machine as well as the very material out of which the body is constructed, man's diet must be seriously considered not only during the years of growth, when the drain on the body's resources is commonly supposed to be peculiarly severe, but also throughout his working years. The facts have been bluntly, yet effectively expressed by saying that under natural conditions of trade the working man brings into the market his energy—his power of doing work—and obtains for it the most favorable price that he can. His ultimate power as a wage-earner is being influenced by the character of his food-supply. His profits depend, on the one hand, on the amount of energy he can supply and the price at which he can sell it, and, on the other, on the price for which he can buy his source of energy—his *food*. We refer here particularly to the wage-earning working man, because the amount of food required depends so largely on the amount of work to be done. An abundance of cheap and good food is the first essential for a productive working class.

The late Professor Atwater and his associates in this country have devoted much attention to the food requirements of the working classes and to the cost of living involved thereby. The standards thus obtained have proved of great value in sociologic studies. Examining the conditions in New York City a few years ago, Professor Underhill found that at that time it required an expenditure of considerably more than twenty cents a day to secure the nutriment adequate for the working classes investigated. Small indiscretions in the direction of inexpedient purchases of food readily raised the cost of the minimal requirement. In collaboration with Prof. Noël Paton, Miss Dorothy Lindsay[1] has carried out a most interesting study of the diet of the laboring classes in the city of Glasgow, Scotland, during 1911 and 1912. The inquiry was directed to ascertain whether the working classes of that city get such a diet as will enable them to develop into strong, healthy, energetic men and enable them to do a strenuous day's work, or whether the conditions of the laboring classes are such that a suitable diet is not obtainable. Furthermore, attention was directed to the pertinent question as to whether, if a suitable diet is obtainable, its cost is low enough to leave a margin of income sufficient to cover the other necessary expenses of the family life, with something over for those "pleasures and amenities without which the very continuance of life is of doubtful value."

The Glasgow report, like others that have preceded it, shows how important such investigations are at the present time. In view of the agitation in many quarters for compulsory insurance, it is well to bear in mind as Dr. Paton points out, when dealing with the almost dependent classes, that a very small contribution even for problematic benefits in future years may decrease the expenditure on the family diet, and the benefits may thus be bought at too great a price.

Accepting the standard of energy requirement adopted by the Glasgow investigators, it appears that in the case of the really poor—*those who* have a daily struggle to make both ends meet—*even although*, as the statistics show, three-quarters of their meager income is expended on food, a sufficient supply is not obtained, and that the remaining fourth of the income is quite inadequate to defray the necessary outlay on rents, coal, taxes, insurance, etc., while absolutely nothing is left for expenditure on amusements of any kind. The families in which the income is under 20 shillings a week entirely fail to obtain a supply of food sufficient for their needs. Some of the actual facts discovered are worth reciting here. The average daily energy value of all the diets of workingmen's families studied in Glasgow was 3,163 calories, including 110 gm. of protein, 83 gm. of fat and 473 gm. of carbohydrate. Of the protein about two-thirds came from vegetable sources. The principal foods used were bread, potato, milk, sugar, beef and vegetables, such valuable and easily procured products as oatmeal and peas being used in relatively small amounts. Not one of the families in which the wage was regular and under 20 shillings per week had a diet the energy value of which reached the minimum of 3,000 calories per adult man. With increase in income, however, the energy content of the dietary advanced.

One naturally asks what can be done to improve such diets, since it is not within the province of the dietitian directly to alter the financial return to the families. It appears on closer survey of the situation that ignorance and bad marketing play their part as well as penury. The protein-rich animal foods, flesh, fish and eggs, are all too expensive for the laboring classes, and any increase in their proportion in the diet is impracticable. The Glasgow physiologists wisely point out that cheese and the cheap protein-rich vegetable foods, oatmeal, peas, beans, etc., should be more freely used. The chief drawback of the latter is the labor entailed in preparing and cooking them. Here lies an opportunity for a wholesome reform in the technic of the food industries. If the diet of the laboring classes is to be improved decidedly, without increasing the cost, time and labor must be expended on properly preparing the more nutritive foods of vegetable origin for the ready use of man.

Dr. Paton believes that the experiences in Glasgow and Edinburgh teach the same lesson—that what is needed is a partial return to the national dish of porridge and milk, in place of tea, bread and jam which have so universally replaced it in towns and are winning favor even in the rural districts. There is probably little advantage in preaching the value of these old-fashioned dishes. Presumably nothing short of exhibiting the value of different foods, of training in marketing and cooking in schools will have an influence on the future. There is an opportunity here for a splendid propaganda on how to spend money for food to best advantage and how to cook it in the most palatable form. These are not fads; they are the essence of life in a keen struggle for existence.

---

MILITARY INSTRUCTION FOR MEDICAL STUDENTS

At Gettysburg, Pa., from July 7 to Aug 15, 1913, and at Monterey, Cal., from July 1 to Aug. 8, 1913, two military-instruction encampments were held, attendance at which was permitted only to students from non-military schools. The War Department in projecting these camps, held in consideration the plan, should this experiment be successful, to hold similar encampments annually in each section of the country. The object sought is to augment our small military reserves by a well-trained class of men from whom in time of national emergency a large proportion of commissioned officers could be drawn.

All students physically qualified and properly recommended, who are over 17 years of age, may volunteer for these camps and for the time being must render themselves subservient to military discipline. Instructions and exercises include the application of proper health precautions in camp and on the march, personal hygiene, instruction in military tactics and handling of troops under the conditions of battle. Instruction is also afforded in the care of troops in the field, in the duties of the officers of the medical corps during an engagement with the enemy, on the proper way of removing the wounded from the battle-field to the rear, and on allied subjects. Instruction in shooting is provided and the regular badge for markmanship of the National Rifle Association of the United States is bestowed on those students who make the requisite score. Afternoons and evenings are at the disposal of the student, subject to proper supervision and to military necessity. Opportunity is afforded for acquiring horsemanship and practice is given in riding artillery caissons and horses. Students coming from one institution of learning, if they desire, will be allowed, so far as it is practicable, to be members of one company and will be permitted to share one or adjoining tents. Men selected from among the students will be appointed aids to the company commanders.

The student is thus given a healthy outdoor life for the summer at less expense than is usually required; he acquires habits of obedience, command, self-control, order and personal hygiene; he gains the benefit received from intercourse with students of other institutions, and he has an opportunity to become skilled in athletics and to obtain a knowledge of military art. A certificate is given to each student who attends throughout the entire encampment. Details as to needed equipment, uniform, etc., will be supplied on application to the War Department.

It would unquestionably be well for medical students to volunteer for admittance to these camps. The advantages offered are obvious to the ambitious student desirous of becoming a military surgeon. Those unambitious in this direction would gain an experience of sanitary measures which would be helpful in routine medical practice.

THE THEORY OF ARSENIC THERAPY IN ANEMIAS

Arsenic is one of the drugs most frequently prescribed in various forms of anemia and is probably the one on which the great majority of physicians still rely in the treatment of certain types. Whether or not this therapy has any considerable influence over the course of a disease like pernicious anemia, and even whether or not it is always free from objections, may well be open to question. Although iron and arsenic are commonly depended on to hasten the process of blood regeneration, the entire question of the mode of their action is decidedly obscure. It is always difficult, if not impossible, to estimate to what extent rest and nutrition—in other words, good hygienic measures—contribute to the outcome ascribed to the "stimulating" or "tonic" effect of drugs of the class here included, which is politely clothed with the designation "alterative."

At one time we were taught to assume that arsenic initiates the new formation of blood by virtue of an action directly on the hemopoietic organs, notably the bone-marrow. This point of view has been in part abandoned of late in so far as the marrow has been looked on as the immediate seat of stimulation by the drug. Arsenic is a blood-poison and is currently believed to lead to a destruction of red corpuscles in the peripheral regions of the circulation. Hemolysis and loss of erythrocytes are, however, of themselves provocative of regenerative processes. The organism responds to lack of blood elements and loss of oxygen-carrying power in the circulation by the production of new corpuscles. On this basis we may accordingly believe that arsenic induces a restoration of blood elements not because it directly stimulates the localities concerned in their production, but rather because by causing an actual destruction of corpuscles it indirectly furnishes the occasion for a secondary vigorous compensatory repair of the damage.

Is this hypothesis tenable? Does arsenic act on the blood alone or on the blood-forming organs? The participation of the latter, when it occurs, is made manifest by the presence of "youthful" types of blood-corpuscles, newly formed erythrocytes in the blood. These cells have morphologic features in the guise of nucleated characteristics which betray them to the microscopist. Even more significant, perhaps, is another mark of "newly made" blood, such as that encountered in the regeneration which attends anemias. Morawitz and others have shown that the erythrocytes of circulating blood under normal conditions exhibit no phenomena of "respiration," that is, oxygen consumption. In anemia, however, there is a very marked absorption of oxygen and production of carbon dioxid on the part of the blood-cells. This is so conspicuous and characteristic of regenerated blood that it can frequently be detected chemically even when the morphologically characteristic nucleated or polychromatic new erythrocytes cannot be discerned. Here, then, is a "test" for the occurrence of regenerative changes in the blood. When it is applied to the behavior of the blood after administration of arsenic the facts observed are the following:[1] Large, toxic quantities produce a mild anemia. The arsenical anemia is hemolytic in character and attended by active compensatory regenerative responses which can readily be detected by the method of estimating oxygen-consumption just referred to. On the other hand, when small doses of arsenic comparable with what are employed in human therapy are experimentally administered to animals, there is no evidence of initial anemia or of consequent regeneration. These facts speak clearly against the theory of compensatory regeneration ascribed to the action of arsenic on the blood in therapy. Investigations with the outcome here noted do not serve to place arsenic therapy for these cases on a more rational or stable basis. It must be remembered, however, that the process of blood-regeneration may be affected differently in health and in disease. It is quite possible that the effects of arsenic which seem to occur clinically must be sought in an influence on conditions that specially prevail in the diseased, in contrast with the healthy organism.

CHEMICAL CONSEQUENCES OF THE REMOVAL OF THE PARATHYROID GLANDS

The complete removal of the parathyroid glands is attended with fatal consequences. This experimental fact speaks decisively with regard to their importance for the maintenance of the bodily functions; it does not, by itself, give any indication of the mode in which the parathyroidal tissue determines the healthy continuance of the normal processes in the organism. As has been done in the case of other so-called glands with internal secretion, so here we may assume that they act in one of several ways—either they furnish some regulatory or stimulating product (a hormone) which is distributed to appropriate parts of the body, or they may act as antitoxic agencies, neutralizing, modifying or destroying products which would otherwise be harmful to the individual.

The most prominent symptoms of abnormality which attend the removal of the parathyroids are perhaps those of tetany. This is of itself suggestive, though by no means demonstrative, of the participation of a toxic agent in the physiologic events caused thereby. The discovery of toxic bases in large quantities in the urine of parathyroidectomized dogs by Dr. Koch[2] at the University of Michigan is therefore of more than passing interest. In every case studied methylguanidin was present in the secretion of the kidneys. When this substance was found in smaller quantities, other guanidin bases were present, so that the excreted guanidin nitrogen approached a constant. In addition to these bases others were observed, namely, beta-imidazolylethylamin, cholin, neurin and unidentified bases, although these were not distributed uniformly in the cases studied.

The histologic picture which appears in the tissues of parathyroidectomized animals is one of cellular disintegration, particularly in such organs as the liver, kidney and brain. Various degrees of chromatolysis are observed in the nuclei, and in some places the latter disappear entirely in large areas. Koch suggests that the passive protein destruction which must accompany such tissue changes may give rise to basic products and thus account for the unusual compounds excreted. Inasmuch as in animals which have been operated on the specific toxic symptoms can be provoked by the feeding of digested protein, it may be that the toxic effects are initiated by products of intestinal or even of parenteral digestion. Normally these derivatives are incorporated in some cell molecule or stored up in some form. In the case of parathyroidectomized animals after feeding digested proteins, it is suggested that the products remain free and act as toxins. In animals operated on when no feeding occurred the symptoms increased in violence with short intermissions until death. The intensity of the symptoms doubtless followed the rate of disintegration of body protein. The pathologic condition would thus appear to be a failure on the part of the cells to build up their protein. This part of the metabolism of the cell, Koch reminds us, is regarded as the function of the nucleus. Such indications, together with the formation of free "nuclein" components, point to a nuclear atrophy. The histologic findings, moreover, show an active "nuclein" degeneration. The reputed relation of the parathyroid to calcium metabolism and the theories of glandular function built up on it have not made effective progress of late. One is not justified at present in saying that these are quite unfounded. Doubtless in the complex disturbances set up by so serious an operation as the complete exclusion of vitally important glands the interrelated consequences are varied and numerous. The outcome of the discovery of the toxic bases in the urine is the suggestion of Koch that the parathyroid secretion appears to be concerned also with anabolic processes related to the synthesis of nuclear contents. Whether or not such a hypothesis can be further substantiated remains to be seen; in any event the final successful isolation of recognized toxic chemical products of traceable origin has paved the way to definite conceptions and specific lines of inquiry where hitherto the explanations have been vague and the outlook unpromising.

The Inaugural Symptoms of Gall-Stones.—The error that has found a place in the minds of all medical men, and has been faithfully carried down from one generation of text-books to another—that in the majority of cases gall-stones cause no symptoms—has been forever dispelled by the work of the surgeon. In operating in cases of advanced cholelithiasis a history of inveterate though perhaps trivial dyspepsia over a long period can almost always be obtained.—Sir Berkeley Moynihan, Address in Surgery, Brit. Med. Assn., 1913.

Current Comment

A LAYMAN'S ADVICE ON ORGANIZATION METHODS

Suggestions of value to our medical societies can often be obtained from civic organizations. In a recent issue of *Suburban Life* Mr. H. J. Howland entertainingly and instructively recites his experiences as president of the Civic Association of Montclair, N. J. "The point," Mr. Howland says, "is to begin with something definite and not too hard, something that needs not discussion but doing. If you have a civic association or improvement society [or, he might have added, a medical society] there is one thing you must avoid like the plague—the adopting of resolutions. The resolution habit is worse than drink, worse than the opium habit. In my brief and inglorious career I put many resolutions to vote, saw them adopted with enthusiasm, and then decorously interred in the archives until I shuddered at the thought that New Year's Day was *coming*. Do not pass resolutions. Get out and do things." Better advice to our medical organizations could hardly be conceived. Medical societies have from time immemorial been afflicted with the resolution habit. Simply passing resolutions never did anything. If there is something that ought to be done in city, county, state or nation, let us not pass resolutions, but if it can be done, let us go and do it.

NARCOSIS AND LACK OF OXYGEN

In a recent discussion of the nature and underlying factors of anesthesia,[1] reference was made to one of the current views, championed particularly by Verworn, which maintains that a lowered oxidative function of the tissues is responsible for the anesthetic manifestations. On this hypothesis anesthesia would practically be equivalent to a sort of asphyxiation of the cells under the influence of the narcotic. Various telling objections have been offered in criticism of this point of view. It is true that there may be an intimate relation at times between the appearance of narcosis and a tendency toward deficient oxygen-supply in the tissues; but the two factors are by no means interdependent. Narcosis cannot be explained simply on the basis of an inhibition of oxidation, inasmuch as the possibility of narcotizing an individual is not inevitably associated with the existence of oxidative changes in the organism involved. This has now been demonstrated in a convincing way in the case of animals which exist quite independent of respired oxygen, namely, the anoxybiotic intestinal parasites.[2] It is quite easy to keep the familiar intestinal roundworms, ascarides, alive and active in unoxygenated fluids, and still to narcotize them with alcohol or chloroform. They can thereupon be revived again by transfer into fresh fluid mediums without the participation of added oxygen at any time. The inhibition of oxidation in the higher forms of life must therefore at best be only an incident in the genesis of narcosis, not the fundamental determining feature.

CONCERNING "FRIEDMANN VACCINE"

We recently referred[1] to the report of Dr. Barnes of the Rhode Island State Sanatorium for Tuberculosis on his results with the Friedmann vaccine. A complete abstract of this report is given in this issue.[2] It merely adds to the mass of information that goes to make up the literature concerning Friedmann's attempt at exploiting the consumptive, all of which shows the Friedmann treatment to have no advantage over other methods of treating tuberculosis; in all probability, it is even a dangerous one. The medical profession has, until recently, maintained toward this product an attitude of reasonable scientific skepticism. In view of the fact, however, that it seems impossible to find a single reliable favorable report, the time has come for us to cease hoping that in the Friedmann vaccine we have a cure for tuberculosis. Moreover, since the methods of exploitation have become so obviously commercial, with what seems to be an utter disregard for the humanitarian viewpoint, the time surely has come for not only a definite stand against the sale of this product but for positive opposition to the methods used by those financially interested in its promotion. Friedmann secured the financial results which wide-spread newspaper exploitation brought him, and slipped away, leaving a host of "Friedmann institutes" to divide with him the dollars of the too hopeful and credulous sufferers. These "institutes" are being organized in various parts of the country and the personnel of these organizations in practically every instance is sufficient to suggest their true nature. Steps have been taken in several states to check this exploitation of the consumptive for commercial gain, especially in Idaho, Iowa and Arkansas. In others, the weakness of local ordinances has made this impossible. What is now needed is that these unscrupulous attempts should be met with an intensive campaign of education of the public concerning the dangers and worthlessness of this treatment.

THE PRESIDENT'S PROGRAM AND A DEPARTMENT OF HEALTH

President Wilson evidently believes that party platforms are made to be carried out and not merely for the purpose of winning elections. According to Washington newspaper correspondents, it is Mr. Wilson's intention to carry out the promises of the Baltimore platform during the next session of Congress. A recent dispatch from Washington in the Chicago *Tribune* says:

> "The President has insisted that during the pending special session, the Democrats revise the tariff and reform the currency. This will leave them free during the next session and the regular session a year hence to pass bills strengthening the Sherman law so as to destroy the trust evil, conserving natural resources and granting ultimate independence to the Philippines, providing employees' compensation within federal jurisdiction, creating reforms in the civil and criminal laws, limiting the amount of campaign contributions and providing publicity before elections, improving and developing the Mississippi River, and establishing a national health service."

This program includes the principal promises of the Democratic party made before the last election. The public health plank of the Baltimore platform is easily the strongest declaration on this subject which has been made by any political party:

[2] Society Proceedings, p. 1086.

> "We reaffirm our previous declaration advocating the union and strengthening of the various governmental agencies relating to pure foods, quarantine, vital statistics, and human health. Thus united and administering without partiality to or discrimination against any school of medicine or system of healing, they would constitute a single health service not subordinate to any commercial or financial interests, but devoted exclusively to the conservation of human life and efficiency. Moreover, this health service should cooperate with the health agencies of our various states and cities without interference with their prerogatives or with the freedom of individuals to employ such medical or hygienic aid as they may see fit."

This statement, which amply defines the scope and function of such a national department of health as is desirable, and yet fully safeguards the rights of each individual and satisfies the objections of any honest critic, is evidently regarded by Mr. Wilson as one of the most important planks in his party's platform. The inclusion of a national department of health in the administration program cannot fail to be gratifying to all of the advocates of better federal health organization. The discussion of this subject during the past three years has been of immense educational value. The prospects for practical, constructive legislation, providing for an enlarged health machinery as a part of our federal government, are better to-day than ever before. The duty and the opportunity of the medical profession and of medical organizations are clear. Let us be prepared unselfishly and without partisanship to give public-spirited assistance to the administration in devising plans for a national department of health that will be a safeguard to the people against disease and will command the support of all intelligent and public-spirited citizens.

THE OZONE INVESTIGATIONS

Some months ago we received an advertisement of an ozone machine from a large high-grade concern which makes such machines merely as one of the many electrical devices it puts on the market. Previous to this we had been proffered advertisements of many ozone machines as therapeutic agents. These advertisements had been refused, principally because the advertising "literature" issued by the concerns selling the machines was so extravagant and absurd that there was no doubt as to the fraudulence of the devices. The claims made for the machine first referred to, however, were not extravagant and the question then arose as to what good there was in such machines. We asked for evidence on this point, but that submitted was not satisfactory. We concluded, therefore, that it was time to investigate the matter and asked Professors Jordan and Carlson to take it up for us. This they did. When their report was in type and about to be published a report of similar work was received from Drs. Sawyer, Beckwith and Skolfield of San Francisco. It was then decided to hold back the first report so as to have the two appear together, which they do in this issue. The two groups of investigators were working independently and neither knew that the other was attacking the problem. The subject is discussed also on a preceding editorial page.

ETHICS!

"We will pay you $25 for each patient that you bring or send us." Thus, to physicians, writes the Hord Sanitarium of Shelbyville, Indiana, and continues: "We have a perfect and an absolute cure for all liquor and drug addictions." Fearing doubtless that those to whom these offers are made may be disgusted with the first proposition and will realize the evident falsity of the second, the concern encloses a list of references "showing the high moral and professional standing of our sanitarium." The Hord Sanitarium emphasizes further that it does a strictly "no cure no pay" business. Suspiciously similar is the offer made by the Mizer Sanatorium of Coshocton, Ohio, Blake V. Mizer, manager. Not many months ago Mr. Mizer was running the Hord Sanitorium (the concern's own spelling), which at that time advertised "the only guaranteed cure." Now, Mr. Mizer hurls invectives at those concerns that make "unreasonable guarantees" and adds virtuously that "we resort to no such unethical and pretended guarantee in order to do business." Nevertheless, in small type in the northwest corner of his stationery, Mr. Mizer admits that his "proposition" is no cure no pay. The fees of the Mizer Sanatorium "are $125 to $250, depending on the room." The physician's rake-off is "20 per cent. of the above." "This," explains Mr. Mizer blandly, "is simply a matter between ourselves and does not concern the patient in any way." Of course not. All the patient has to do is to pay the bills. And the Mizer Sanatorium is "conducted along ethical . . . lines"—Mr. Mizer says so. The Mizer Sanatorium has odd ideas of what constitutes ethics, medical or otherwise, for not long ago it advertised, in such medical journals as would accept its "copy," that "medical ethics prevents the statement here of the whole truth about the Mizer treatment." Of course medical ethics never prevented truthful statements of any kind. A dirty business; no other words express it. When the Hord Sanitarium and the Mizer Sanatorium claim to cure all cases of drug or liquor addiction, they make claims that are false—cruelly false. When these concerns try to drum up trade by offering secret commissions to physicians they insult an honorable profession. The fact that they send out this sort of advertising matter is presumptive proof that there are some physicians who will patronize them. Such as do so are unfair to their patients and untrue to the ideals of medicine.

HYDROCYANIC ACID FROM DECOMPOSING PROTEINS

Some new questions relative to the significance of the finding of hydrocyanic acid in animal tissues are raised by observations just published from the departments of chemistry and bacteriology at the University of Kansas. Emerson, Cady and Bailey[1] have ascertained that certain micro-organisms living on protein mediums can evolve hydrocyanic acid. Clawson and Young[2] have identified the active agent in the cases investigated as the *Bacillus*

---

1. Emerson, H. W., Cady, H. P., and Bailey, E. S. H.: On the Formation of Hydrocyanic Acid from Proteins, Jour. Biol. Chem., 1913, xv, 415.

2. Clawson, B. J., and Young, C. C.: Preliminary Report on the Production of Hydrocyanic Acid by Bacteria, Jour. Biol. Chem., 1913, xv, 419.

pyocyaneus. This is, however, not the only organism found which can produce the volatile acid from proteins. The HCN-producing organisms do not liberate the poison in mediums containing free mineral acid. The facts here reported cannot fail to interest toxicologists who have scarcely been prepared to expect hydrocyanic acid as a substance liberated from decomposing proteins, though it has frequently been mentioned as a product of enzymatic reaction. The possible medicolegal bearings remain to be learned.

Medical News

ILLINOIS

Sanatorium Campaign Launched.—The Sisters of Mercy eight-day campaign for $100,000, which is to help pay for a home for girls and a sanatorium for the Home for the Aged, to be located in Aurora, was launched September 16. Already there has been $10,000 subscribed and Bishop Muldoon has promised that he would give $1,000 for every $10,000 raised by the people of Aurora and vicinity.

Personal.—Dr. Charles F. Sanborn, Chicago, has succeeded Henry L. Bailey as warden of the Cook County Hospital.——Dr. W. P. Woodard, Cherry Valley, sustained painful injuries of the wrist while leaping from a street car, September 12.——Dr. and Mrs. H. S. Worthley, Joliet, have returned from Europe.——Dr. Oscar B. Edmondson, Clinton, was operated on September 10 for appendicitis and is reported to be doing well.——Dr. Isaac Moore, Alton, suffered a cerebral hemorrhage at his home, September 9.

Chicago

Educational Campaign Against Tuberculosis.—The Chicago Tuberculosis Institute opened a two-week tuberculosis exhibit in Sherman Park, September 13. Health talks are being given each afternoon and evening to disseminate information regarding tuberculosis, its prevention and treatment.

Personal.—Dr. Clara Moore, for several years resident physician and pathologist in the North Chicago Hospital, has been appointed instructor in clinical medicine and diagnosis in the medical department of the University of Wisconsin, Madison.——Dr. and Mrs. William A. Evans left for the Northwest, September 17, on a lecture tour of Western Canada. They will return to Chicago about October 1.

MASSACHUSETTS

Floating Hospital Season Ends.—The Boston Floating Hospital has closed the busiest season on record. In the permanent wards 6,323 days' care were given to babies and 4,149 days' service to outer-deck patients. The work of the hospital on shore will be continued during the autumn and winter, as it was last year.

Personal.—The following associate medical examiners have been reappointed: Dr. John W. Pratt, Dedham, for Norfolk County; Dr. Francis E. Johnson, Erving, for Franklin County, and Dr. George A. Bancroft, Natick, for Middlesex County.——Dr. Stanton J. Ten Broeck, Orange, has been reappointed medical examiner for Franklin County.——Dr. Charles F. McCarthy, Winchester, has been appointed medical examiner of the Fourth Middlesex district.

Baby Hygiene Association Report.—George R. Bedinger, director of the Milk and Baby Hygiene Association, Boston, reported that during August 1,669 infants had been cared for by the association, an increase of 30 per cent. over August, 1912. The total of new patients cared for during the month was 317. There were forty-nine baby clinics held at the eleven milk stations of the association with a total attendance of 1,612. The association feels that funds should be raised to keep some of the stations open throughout the year.

MICHIGAN

New Hospital.—The new Manufacturers' Mutual Hospital, Detroit, was formally opened September 2. The institution has twelve beds and is provided with ample facilities for the treatment of accidents and emergencies.

Military Surgeons at County Society.—The Houghton County Medical Society at its monthly meeting September 1 had as its guests of honor the members of the Medical Corps of the Michigan National Guard on duty in the copper country. Major R. C. Apted, Grand Rapids, acting chief surgeon, read a paper on "Active Medical Service in the Field"; Major John V. Frazier, Port Huron, described the organization of the field hospital; Captain Ernest C. Lee, Detroit, spoke on the "Ambulance Company," and Captain R. J. Baskerville, Detroit, gave a detailed explanation of the use of the first-aid outfit, the general equipment, cooking of meals in the field, etc.

State Society Meeting.—The forty-eighth annual meeting of the Michigan State Medical Society was held in Flint, September 3-5. The following officers were elected: president, Dr. Guy L. Kiefer, Detroit; vice-presidents, Drs. H. E. Randell, Flint; E. C. Taylor, Jackson; E. H. Webster, Sault Ste. Marie, and R. H. Spencer, Grand Rapids; delegate to the meeting of the American Medical Association, Dr. E. T. Abrams, Dollar Bay; alternate, Dr. W. H. Hewlett, Detroit; members of the council, Dr. A. E. Bulson, Jackson, second district (reelected); Dr. R. S. Buckland, Baraga, twelfth district, succeeding Dr. A. J. Annis, Sault Ste. Marie, and secretary, Dr. F. C. Warnshuis, Grand Rapids (reelected).

NEW YORK

Tuberculosis Sanatorium Planned.—The State Department of Health has given permission for the operation of a sanatorium at Harrietstown, near Lake Placid, in the Adirondack Mountains.

Personal.—Dr. and Mrs. George F. Blauvelt, Nyack, have returned from Europe.——Dr. F. P. Hough, Binghamton, who was seriously injured in an automobile accident, September 1, is reported to be convalescent.

Medical College Will Build.—Although the Albany Medical College received only $10,000 instead of $100,000, as was expected in the will of the late Dr. John M. Bigelow, it will go on with the plans already made for the construction of the laboratory building. The Bigelow bequest provided for the establishment of the chair of laryngology and rhinology, and in addition the Bigelow stock in the college is to revert to the institution, the income to be applied for the best senior examination in diseases of the throat and nose.

Street Accidents in August.—The National Highways Protective Society in its last report shows that during the month of August there were in the state, outside of New York City, 13 persons killed and 161 injured by automobiles, 7 killed and 64 injured by trolleys, and 3 killed and 20 injured by wagons. In New York City during the month there were 47 persons killed and 204 injured in street accidents. Automobiles caused the death of 22 persons and injured 118, trolleys killed 13 and injured 53, while wagons killed 12 and injured 33. During the corresponding month last year automobiles caused 18 deaths, trolleys 13 and wagons 17.

New York City

Personal.—Dr. Francis O'Brien, ambulance surgeon of St. Mary's Hospital, Brooklyn, was seriously injured in an accident which wrecked the motor-ambulance of the hospital September 6.

Harvey Society Lectures.—The annual course of lectures under the auspices of the Harvey Society begins October 4 with a lecture by Dr. Augustus D. Waller, F. R. S., entitled "A Short Account of the Origin and Scope of Electrocardiography." Dr. Waller is a pioneer in animal electricity, was the first to record human electrocardiograms and brings with him his own apparatus, which he will demonstrate during the lecture.

To Increase County Society Membership.—The Special Committee on New Members of the Medical Society of the County of New York has sent out a letter to all members urging each to enlist at least one physician who is eligible to membership in the society. The membership at present is 2,515, and it is estimated that there are 1,500 additional physicians in the county who are eligible. While it is impossible for the committee to reach all these, it is believed that if the members take a personal interest in the matter the membership of the society can be considerably increased, even though it will lose 176 members through the formation of the Medical Society of the County of the Bronx.

The Service of Summonses by the Health Department.—Until recently summonses for the violation of the sanitary code have been served by a police officer attached to the Department of Health, but a resolution adopted by the Board of Health at its meeting on August 26 has changed this method of procedure. In order to facilitate the work of the inspector and to save him a trip to court he is permitted to serve a summons immediately without consulting a magistrate. It had also been found in the past that a number of offenders against the sanitary code disappeared while the inspector was engaged in obtaining summons. This change in procedure has been made possible by a recent amendment in the Greater New York charter.

Typhoid Outbreak on East Side.—Less than a month ago the city was congratulating itself on having the fewest number of typhoid fever cases this year that have ever been recorded, while now it is alarmed over what is probably the worst epidemic of the disease that this city has experienced in fifty years. In the affected district 178 cases of typhoid fever have been reported since the first of the month. The district lies east of Third Avenue and between Third and Thirty-Third streets. Seventy-two of the reported cases are in Bellevue Hospital. The Health Department has traced the source of the infection to one milk supply and efforts are being made to locate the dairy from which the contaminated supply has been received. The Health Department offers immunizing treatment to all the members of families in which cases have developed, but it is said that the east-siders are not eager to take advantage of this offer.

NORTH CAROLINA

Personal.—Dr. W. I. Royster, Raleigh, who was seriously injured by being struck by a passing vehicle, is convalescent and is able to attend to business.——Dr. Hubert A. Royster, Raleigh, Drs. J. P. Munroe, C. M. Strong, A. J. Crowell and C. N. Peeler, Charlotte, have returned from Europe.

Insane Hospital Report.—The quarterly report of Dr. John McCampbell, superintendent of the Western Hospital for the Insane, Morgantown, shows the present number in the institution to be 1,342, with more than 300 applications on file. The new building for women, for which $50,000 was appropriated by the last legislature, is under construction and will offer accommodation to 150 patients.

PENNSYLVANIA

Personal.—Dr. Howard H. Bell, former intern at the City Hospital, Harrisburg, has accepted the position of demonstrator of pathology at the University of Alabama, Mobile.

Philadelphia

Memorial to Dr. Steinbach.—A new building for the Young Men's Hebrew Association will be erected as a memorial to Dr. Lewis W. Steinbach. Of the $100,000 fund to be raised for this purpose, $60,000 has already been subscribed.

Personal.—Dr. Henry E. Radasch, assistant professor of histology and embryology at Jefferson Medical College, has been appointed instructor of anatomy in the Pennsylvania Academy of Fine Arts to succeed the late Dr. George B. McClellan.

English Physicians in City.—Dr. Ralph Crowley, of London, and Dr. John Sinclair, of Essex, England, were the guests of Dr. Walter S. Cornell at City Hall, Philadelphia, September 16, where they were shown the local system of school medical inspection.

Diseased Throat Conditions Among Schoolchildren.—Among the pupils of the public schools, diseased throat and nose conditions rank second in number to decayed and diseased teeth. Recommendations to parents that these conditions be corrected in their children were made in 22,946 instances by medical inspectors during the last half of the 1912 school year, making 23 per cent. of all the recommendations made by the inspectors during that period.

Hospital Report.—The annual report of the Maternity Hospital at 734 South Tenth Street, recently issued, shows that in the thirty-seven years that the hospital has been in existence 3,896 babies have been born, with a record of only 211 deaths of infants and 38 deaths of mothers. This hospital cares for the woman before the period of her confinement, through the agency of the Midnight Mission, and after the birth of the baby the mother and child are sent to the Sheltering Arms and positions are obtained through the Children's Aid Society.

WEST VIRGINIA

Personal.—Dr. Charles B. McGlumphy, Moundsville, has returned from Europe. He has been appointed professor of bacteriology in the University of Texas, Galveston.——Dr. H. L. Gray has been appointed assistant physician at the State Insane Hospital, Weston, vice Dr. J. G. Pettit, resigned.

State Tuberculosis Exhibit.—The Antituberculosis League of West Virginia is about to send a car throughout the state with a free tuberculosis exhibit. It is the intention to visit one or more places in each county where lectures will be given and moving pictures shown relative to tuberculosis. The railways of the state have given a car and free transportation over their lines.

WISCONSIN

Hospital Notes.—The Board of Health of Racine has accepted for the city the new isolation hospital just completed. The building has cost $4,100 and has accommodation for eight to ten patients.

Visiting Nurses for Tuberculosis.—The first county visiting nurse in Wisconsin to take up tuberculosis work began in Milwaukee County September 15. Additional nurses will be employed as required.

New Officers.—Second District Medical Society, tenth annual meeting at Racine, September 5: president, Dr. George H. Young, Elkhorn; secretary-treasurer, Dr. Milton V. Dewire, Sharon. It was decided to hold the 1914 meeting in Walworth County.

State Society Meeting.—The annual meeting of the Wisconsin State Medical Association will be held in Milwaukee, September 29 to October 3.——On September 30 and October 1, the Wisconsin Medical Women's Society will hold its fourth annual meeting in Milwaukee, with headquarters at the Hotel Pfister.

Personal.—Dr. Belle P. Nair, Fort Atkinson, has been appointed resident physician at the Northern Hospital for the Insane, Oshkosh.——Dr. Robert Curtis Brown has been elected chief of staff of the Milwaukee Society for the Care of the Sick.——Dr. W. C. Bennett, Oregon, has been appointed physician to the State Reformatory.

Camps for Tuberculosis.—The State Board of Control recently visited Minocqua to look over prospective sites for the new tuberculosis camps, for the maintenance of which the state has made an appropriation of $10,000 a year.——The proposed Milwaukee County Tuberculosis Sanatorium at Wauwatosa is to cost not to exceed $396,000, and not $600,000 as originally called for by the plans.——The new Outagamie County Sanatorium near Kaukauna is nearing completion. The building is 136x72 feet, is of concrete and wood construction, and will accommodate about thirty patients.——The fresh air camp established near Neenah for the summer was closed September 3.

University Establishes Bureau of Health Instruction.—The Extension Division of the University of Wisconsin has established a Bureau of Health Instruction for popular education in health and disease. According to the announcement, it is the purpose to extend this information on the part of the general public by means of lectures, publications, exhibits and correspondence. In the case of communities, surveys of existing conditions will be made, upon which working plans may be based for water system, sewage and general health regulation and administration. An exhibit is being prepared which will be sent from place to place throughout the state as opportunity and demand warrant.

GENERAL

Eye, Ear and Throat Men to Meet in Chattanooga.—The eighteenth annual meeting of the American Academy of Ophthalmology and Otolaryngology will be held in Chattanooga, Tenn., October 27-29. The address of the occasion will be presented by Colonel R. H. Elliott, I. M. S., Madras, India.

Propose Monument to Confederate Surgeon General.—At the meeting of the Association of Medical Officers of the Army and Navy of the Confederacy in 1909 it was proposed to erect a monument to the memory of Surgeon General James Preston Moore, C. S. A. This movement was indorsed by the United Confederate Veterans and by the Confederated Southern Memorial Association a year later. A monument committee has been appointed and it is proposed to erect the statue in Richmond, Va.

Meeting of Military Surgeons.—The twenty-second annual meeting of the Association of Military Surgeons of the United States was held in Denver, Colo., September 16-19, under the presidency of Surgeon William C. Braisted, U. S. N. The following officers were elected: president, Brigadier-General Charles Adams, N. G. Ill. (retired); vice-presidents, Lieut.-Colonel Jefferson R. Kean, M. C., U. S. A.; Surgeon General Rupert Blue, U. S. P. H. S., and Medical Inspector, George A. Lung, U. S. N.; secretary, Colonel Samuel C. Stanton, M. C., N. G. Ill. (reelected), and treasurer, Major Herbert A. Arnold, M. C., N. G. Pa. (reelected). The place and time for the 1914 meeting were left to the Executive Council with power to act.

Cumberland Valley Physicians Elect.—The Cumberland Valley Medical Society at its annual meeting held in Hagerstown, Md., September 4, elected the following officers: president, Dr. E. Roberts Plank, Carlisle, Pa.; vice-presidents, Drs. E. Tracy Bishop, Smithsburg, Md., E. S. Berry, Shippensburg, Pa., and John K. Gordon, Chambersburg, Pa.; secretary, Dr. John J. Coffman, Scotland, Pa. (reelected); assistant secretaries, Drs. J. Royer Laughlin, Hagerstown, Md., R. M. Shepler, Carlisle, Pa., and E. W. Palmer, Greencastle, Pa., and treasurer, Dr. H. C. Devilbiss, Chambersburg, Pa. It was decided to hold the next annual meeting in Cumberland County, Pennsylvania.

Bequests and Donations.—The following bequests and donations have recently been announced:

Seton Hospital, Spuyten Duyvil, N. Y., $15,000 by the will of Mrs. Mary H. Lawrence.

New York Orthopedic Dispensary and Hospital, $7,500 by the will of Marion DeForest Clark.

Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, $20,000 by the will of Lucy Hunter Baird.

Presbyterian Hospital, Philadelphia, $55,000 by the will of Mrs. Jane McKee, Norris.

Worcester (Mass.) Memorial Hospital, $100,000 by the will of Mrs. Katherine Allen.

Mary Fletcher Hospital, Burlington, Vt., $25,000; Proctor Sanatorium, Pittsford, Vt., $10,000; Home for Aged Women, Burlington, Vt., $2,000; Home for Friendless Women, Burlington, Vt., $2,000; by the will of Charles B. Weatherby, Burlington, after the decease of the testator's wife and brother.

Albany Hospital, $10,000 by the will of Dr. John M. Bigelow, Albany.

The Third International Congress of Refrigeration.—The Third International Congress of Refrigeration, with an attendance of nearly two thousand delegates, over four hundred of whom were from abroad, met in Washington and Chicago, September 15 to continue until October 1. The opening meeting of the Congress was held in Washington where the delegates were welcomed by the President of the United States. After two days' sessions in that city the Congress moved to Chicago where the remaining meetings of the sessions were held. An exposition of refrigerating machinery and chilled products with methods of preserving and storing of food products was also held in connection with the Congress. In the six sections into which the Congress was divided, many papers were read relating to the chemistry and the mechanics of refrigeration. Transportation of chilled products, legislation, and allied subjects were also discussed. Among the papers of medical scientific interest read were the following: "Factors Influencing Changes in the Storage of Butter," "Bacterial and Enzymic Changes in Milk and Cream Kept at 0 C.," "Preservation of Eggs by Refrigeration," "Use of Refrigeration in the Preparation of Dried Cultures of Bacteria," "Effect of Prolonged Periods of Cold Storage on Bacteria in the Tissue of Fish," "Effect of Prolonged Cold Storage on the Chemical Composition of Fish," and "The Relation of Refrigeration to Biological Materia Medica." The chief interest of the Congress, however, was in the commercial, economic, and legal aspects of the refrigeration business and in the relation of the storage of foods to the food supply and the cost of living. Much of the time of the delegates to the convention was occupied in sightseeing and inspection of packing-houses, refrigerating and storage plants, etc.

Examination of Candidates for Assistant Surgeon.—Boards of commissioned medical officers will be convened to meet at the Bureau of Public Health Service, 3 B Street, S. E., Washington, D. C., and at the Marine Hospitals of Boston, Mass., Chicago, Ill., St. Louis, Mo., New Orleans, La., and San Francisco, Cal., on Monday, Oct. 20, 1913, at 10 o'clock a. m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service, when applications for examination at these stations are received in the Bureau. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character. Service in hospitals for the insane or experience in the detection of mental diseases will be considered and credit given in the examination. Candidates must have had one year's hospital experience or two years' professional work. Candidates must not be less than 5 feet 4 inches, nor more than 6 feet 2 inches, in height. The following is the usual order of the examinations: 1, physical; 2, oral; 3, written; 4, clinical. In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment that would disqualify them for service in any climate and that they will serve wherever assigned to duty. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists of examination in the various branches of medicine, surgery and hygiene. The oral examination includes subjects of preliminary education, history, literature and natural sciences. The clinical examination is conducted at a hospital. The examination usually covers a period of about ten days. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order. They will receive early appointments. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Assistant surgeons receive $2,000, passed assistant surgeons $2,400, surgeons $3,000, senior surgeons $3,500 and assistant surgeon generals $4,000 a year. When quarters are not provided, commutation at the rate of $30, $40 and $50 a month, according to the grade, is allowed. All grades receive longevity pay, 10 per cent. in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For invitation to appear before the board of examiners, address "Surgeon General, Public Health Service, Washington, D. C."

CANADA

Personal.—Sir Ryckman Godlee, president of the Royal College of Surgeons of England, is expected in Toronto in November to deliver an address before the Academy of Medicine.——Dr. Harry Morrell, editor of the *Western Medical News*, Regina, has been appointed pathologist of the Regina General Hospital, with Dr. S. Rose as assistant.——Dr. Frederick Etherington, Kingston, Ontario, is one of a commission of three investigating the administration of jails in the province of Ontario.

New Officers.—The Saskatchewan Medical Society: honorary president, Dr. David Low, Regina; president, Dr. George R. Peterson, Saskatoon; secretary-treasurer, Dr. Arthur Wilson, Regina.——Prince Edward Island Medical Associataion, at Summerside: president, Dr. W. J. MacMillan, Charlottetown; secretary, Dr. J. C. Macdonald, Little York.——Aesculapian Society, Toronto: president, Dr. James M. Cotton; vice-president, Dr. Bruce L. Riordan; secretary, Dr. George Elliott; treasurer, Dr. Edmund E. King.

Hospital News.—An unknown individual has offered to build and equip a general hospital for Newcastle, N. B., at a cost of $25,000.——Regina, Sask., is erecting a new wing to its General Hospital.——An order of the Toronto Police Commissioners that all accident cases be immediately conveyed to the new Toronto General Hospital is causing considerable friction in that city.——Toronto is maintaining approximately 220 patients at regular hospital rates in the sanatoriums at Weston and Gravenhurst.

Quebec Sanitary Convention.—The fifth annual Congress of the Sanitary Services of the Province of Quebec was held in Montreal September 18 and following days. Dr. E. P. Lachapelle was the president. Dr. J. E. Laberge, M. O. H., Montreal, urged the necessity of those going to school being taught health matters. Dr. Arthur Simard of Quebec thought that 2,000 babies could be saved from death each year in that province by proper sanitary and hygienic measures. Public lectures were given by Dr. T. A. Starkey of McGill and Dr. C. N. Valin of Laval University.

Public Health in Quebec.—The Provincial Board of Health of the Province of Quebec was organized in 1881 with Dr. E. P. Lachapelle, Montreal, president, and Dr. E. Pelletier, secretary. After twenty-six years these officers still continue in their respective positions. To them is due the excellency of the public health acts of the province. In 1910 the province was divided into ten sanitary districts and six of these have been organized with medical inspectors in charge. These are required to have diplomas of public health and reside in their respective jurisdictions.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Sept. 9, 1913.

Statistics of the Medical Profession

Official statistics have just been published with regard to the number of physicians, dentists, midwives and pharmacists who practice in France. The département de la Seine, which includes Paris, is at the head of the list, with 4,393 physicians, 1,125 dentists, 1,329 midwives and 1,798 pharmacists. The département du Nord comes next with 811 physicians, 97 dentists, 422 midwives and 523 pharmacists. The lower places in this statistical list are held by the départements des Hautes-Alpes, Haut-Rhin and la Lozère. In the Hautes-Alpes there are only 29 physicians, 2 dentists, 33 midwives and 14 pharmacists. Altogether, in France there are 20,809 physicians (making an average of one physician for 2,000 persons), 2,848 dentists, 13,066 midwives and 11,585 pharmacists.

A Monument to Dr. Henry Cazalis

On September 7, in the little cemetery of Ferney, near Geneva, but on French soil, a monument was erected to Dr. Henry Cazalis, known in literature under the pseudonym of Jean Lahor. He was born in 1840 and died in 1909 in Switzerland; but as he wished his remains to rest on French soil, the cemetery of Ferney, the little village where Voltaire once lived, was chosen. Jean Lahor wrote several volumes of poetry, but in the last years of his life the spirit of apostleship awoke within him and he dreamed of a society reinvigorated by social hygiene and popular sense of beauty. Abandoning poetry, he wrote works on science and marriage, cheap foods, cheap dwellings, etc. He also contributed to the popularization among us of the esthetic ideas of the English poet, William Morris.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Sept. 5, 1913.

Personal

K. Buerkner, professor of otology in Göttingen, died on a vacation trip in the Tyrol, September 2, aged 60. He began as privat-docent and director of a policlinic for ear diseases in Göttingen in 1877. In 1885 he was appointed professor extraordinary. His most important works are the "Text-book of Otology" and an atlas of pictures of the membrana tympani. He also assisted in the preparation of a number of compilations and was an associate editor of the *Archiv für Ohrenheilkunde*.

Geheimrat von Baelz died September 1, after a long sickness at Stuttgart, at the age of 64. After having been assistant to the renowned Professor Wunderlich of Leipsic in 1871 and 1872, he accepted in 1875 a call to the Japan Medical School at Tokio, where he first taught physiology and afterward occupied the chair of medicine and gynecology. At the same time he was body surgeon of the crown prince, the present mikado. With reference to the illness of the latter, with which the press was full a few weeks ago, he published an account in the *Deutsche medizinische Wochenschrift* of the illness for which he had treated the Japanese ruler in his time, but with some reservation on account of his previous confidential relation. I can disclose that in his youth the mikado was treated by Baelz for a peculiar form of pulmonary tuberculosis, which later healed completely.

After nearly thirty years of activity in Japan (he married a Japanese lady there), Baelz returned to his home in Stuttgart and devoted most of his time to scientific employment. In 1908 on the invitation of the imperial family he visited Japan for a time. In addition to a long treatise on the side effects of salicylic acid, he prepared a text-book on internal medicine, especially for his classes, and devoted much attention to anthropologic and pathologic conditions and published some very interesting articles on these subjects.

Postgraduate Courses on Social Medicine

By decree of the minister of the interior the provincial presidents throughout Prussia are required to establish medical postgraduate courses in social medicine in their respective provinces. The participants in these courses are then expected on their part to give lectures and exercises in the societies for their neighboring colleagues. The courses will be given financial aid by the government provided that the medical chambers *(Aerztekammer)* interested will appropriate additional funds. As an introduction to these courses, a twelve-day course will be held in Berlin this autumn for those physicians who are to deliver the lectures in the provincial courses.

Hamburg to Loan Radium and Mesothorium to Physicians

A bureau for the distribution of radium and mesothorium has been founded in the Hamburg institute for cancer and tuberculosis research which was founded a short time ago. The object is to secure as large a quantity of these preparations as possible in a short time and place them at the disposal of the public. At present about 150 mg. of radium bromid are on hand; this quantity is to be doubled in about two weeks and there is a prospect of securing further amounts. The preparations are to be loaned to physicians.

Diphtheria in Prussia, 1902 to 1911

The morbidity from diphtheria in Prussia increased from 54,848 in 1905 to 83,821 in 1910, and in Berlin from 1,485 in 1902 to 6,061 in 1910. The number of deaths from diphtheria in Prussia decreased from 14,175 in 1902 to 9,683 in 1910, but in Berlin they increased from 239 in 1902 to 695 in 1910. Calculated for 10,000 living, the relative number of cases in Prussia increased from 15.41 in 1902 to 20.87 in 1910, and that in Berlin from 7.68 in 1902 to 28.58 in 1910. The relative number of deaths in Prussia fell from 4.05 in 1902 to 2.45 in 1910, while in Berlin in the same time it rose from 1.25 to 3.11.

Marriages

Janvier Whitton Lindsay, M.D., Washington, D. C, to Miss Catherine Armyn Crabill, of San Antonio, Mo., July 10.

Nathan B. Eddy, M.D., to Miss Wilhemina E. Ehrens, both of New York City, at Glens Falls, N. Y., September 7.

Albert West Metcalfe, M.D., Mobile, Ala., to Miss Anne Porter Kolb of Birmingham, Ala., September 10.

Lewis Booker, M.D., New Castle, Del., to Miss Kathleen M. Flannagan of Charlottesville, Va., September 3.

Charles P. McKee, Jr., M.D., to Miss Pearl Catherine Losher, both of St. Marys, Ohio, September 4.

Albert Butler Stone, M D., Lamar, Mo., to Miss Bessie Wood Ross of Pilot Grove, Mo., August 21.

Walter E. Caswell, M.D., Brockton, Mass., to Miss Annie S. Cameron, of Halifax, N. S., September 2.

Elmer W. Mosely, M.D., Lincoln, Neb., to Miss Etta Frances Brothers of Chicago, September 3.

Charles Arthur Boyd, M.D., Belpre, Kan., to Miss Cora Belle Klein of Iola, Kan., September 10.

Charles H. Shroder, M.D., Duluth, Minn., to Miss Helen Blau of Covington, Ky., August 23.

Russell V. Thomas, M.D., Manteno, Ill., to Miss Cora Lambird of Newton, Ill., September 10.

Albert K. Detwiller, M.D., to Miss Margaret O'Dowd, both of New York City, September 6.

R. L. Carr, M.D., Greenville, N. C., to Miss Elizabeth Pugh of Arkansas, Ark., September 3.

Sydney Walker, Jr., M.D., to Miss Isabelle Clarke Irwin, both of Chicago, September 16.

Walter T. Bronson, M.D., to Miss Laura May Graham, both of Pueblo, Colo., September 2.

Deaths

Edwin Wilcox Bartlett, M.D. University of Vermont, Burlington, 1866; a fellow of the American Medical Association; for forty-three years a specialist in diseases of the eye and ear, of Milwaukee, and for thirty-eight years local surgeon for the Chicago, Milwaukee and St. Paul Railway; emeritus professor of ophthalmology and otology in the medical department of Marquette University; from 1886 to 1889 a member of the school board and from 1894 to 1900 a trustee of the Milwaukee Public Museum, for four years serving as president of the board; died at his home in Milwaukee, September 11, aged 74.

James Milton Blaine, M.D. Jefferson Medical College, 1881; a member and once secretary of the Colorado State Medical Society; secretary of the Dermatological Section of the American Medical Association in 1899; professor of dermatology and venereal diseases in the Denver and Gross College of Medicine; dermatologist at St. Anthony's and the Denver County Hospital, Mercy Sanatorium and the Jewish National Hospital for Consumptives; editor of *Colorado Medicine;* died at the home of his daughter in Carnegie, Pa., September 7, from cerebral hemorrhage, aged 58.

Richard Van Santvoord, M.D. Bellevue Hospital Medical College, 1875; of New York City; a fellow of the American Medical Association, the American Academy of Medicine and The Harvey Society; visiting physician to the Harlem Hospital; died in the Presbyterian Hospital, New York City, September 10, two days after a surgical operation, aged 60.

Walter Millard Fleming, M.D. Albany (N. Y.) Medical College, 1862; a specialist in nervous maladies and insanity, of New York City, for forty years; once health officer of Rochester, N. Y.; surgeon of the Thirteenth New York Volunteer Infantry and later of the Third Brigade, N. G., N. Y., during the Civil War; one of the founders of the Order of Nobles of the Mystic Shrine; died at the home of his son in Mount Vernon, N. Y., September 9, aged 75.

George C. Laws, M.D. University of Pennsylvania, Philadelphia, 1871; a member of the Medical Society of the State of New Jersey; one of the promoters of the Paulsboro (N. J.) National Bank; died at the home of his son in Philadelphia, September 5, aged 68.

Benjamin Franklin Severs, M.D. Long Island College Hospital, Brooklyn, N. Y., 1888; a member of the Medical Society of the State of Pennsylvania; for two terms a member of the Philadelphia School Board; died at his home in Philadelphia, September 5, aged 57.

Augustus Christian Hetrick, M.D. Eclectic Medical Institute, Cincinnati, 1858; president of the Wellsville (Pa.) National Bank and for more than half a century a practitioner of York County, Pa.; died at his home, September 4, from acute gastritis, aged 78.

Mortimer M. Taplin, M.D. McGill University, Montreal, 1892; a fellow of the American Medical Association and a member of the Rochester (N. Y.) Pathological Society; died in the Rochester General Hospital, September 9, from pneumonia, aged 45.

James Franklin Eddington, M.D. Louisville (Ky.) Medical College, 1878; a member of the Illinois State Medical Society and local surgeon at Enfield for the Louisville and Nashville Railroad; died at his home, September 1, from heart disease.

Charles Joseph McFadden, M.D. University of Pennsylvania, Philadelphia, 1891; a member of the Medical Society of the State of Pennsylvania; died at his home in Pittston, September 3, after an illness of two years, aged 44.

William Van Buren Ezell, M.D. University of Louisville, Ky., 1872; for more than forty years a practitioner of Brazoria County, Tex.; died at his home in Angleton, August 26, from nephritis, aged 62.

J. Waller Ford, M.D. Medical College of Virginia, Richmond, 1876; of Hinton, W. Va.; while watering his horse at Talcott, W. Va., September 4, was kicked in the forehead and died two hours later, aged 57.

John E. Gruber, M.D. Medical College of Fort Wayne, Ind., 1882; for more than thirty years a resident of Isabella Co., Mich.; died at his home in Shepherd, August 31, from cerebral hemorrhage.

Reuben B. Keeran, M.D. Eclectic Medical Institute, Cincinnati, 1879; for twenty-seven years a practitioner of Hancock County, O.; died at his home in Findlay, September 5, from asthma, aged 60.

James Augustus Coyne, M.D. Jefferson Medical College, 1896; of Newark, N. J.; died at his summer home in Sterling, Mass., September 8, from heart disease, aged 60.

Owen A. Palmer, M.D. Hahnemann Medical College, Chicago, 1884; formerly of Warren and Cleveland, Ohio; died at his home in Akron, Ohio, August 21, aged 65.

Edward Worcester, M.D. New York University, New York City, 1851; for 53 years a practitioner of Waltham, Mass.; died in his home, September 2, aged 83.

Charles Hamilton Ballantine, M.D. Jefferson Medical College, 1882; of Philadelphia; died in the Jefferson Hospital in that city September 8, from dropsy, aged 56.

E. H. Fordtran, M.D. Fort Worth (Tex.) University, 1911; formerly of Fayetteville, Tex.; died in San Angelo, Tex., September 3, from tuberculosis, aged 25.

John Russell Morris (license, Nebraska, 1909); a resident of Richardson County, Nebraska, since 1878; died at his home in Humboldt, September 2, aged 63.

Mott J. Gillam, M.D. Bennett Medical College, Chicago, 1886; died at his home in Florence, Kan., July 2, from cerebral hemorrhage, aged 48.

Thomas H. Frey, M.D. Memphis Hospital Medical College, 1899; died at his home in Beaumont, Tex., September 6, from nephritis, aged 48.

Lewis G. Tandy, M.D. Washington University, St. Louis, 1886; died at his home in St. Louis, August 28, from meningitis, aged 51.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

SINKINA

Report of the Council on Pharmacy and Chemistry

Sinkina is a malaria "cure" put on the market by the Metropolitan Pharmacal Company, New York. The product was presented to the Council on Pharmacy and Chemistry for admission to New and Nonofficial Remedies and was rejected because insufficient evidence was submitted to substantiate the improbable claims made for it. The manufacturers were sent a copy of the report stating that their product was refused recognition. In view of the advertising that was persisted in after its rejection, the Council's referee for Sinkina submitted the preparation to clinical tests. Both the original report and the results of the clinical tests are given in the following report, which was submitted to the Council and recommended for publication. The complete report having been sent to the manufacturers and their reply considered, the Council authorizes its publication. W. A. PUCKNER, Secretary.

THE COUNCIL'S FIRST REPORT

The Council, after investigating the claims made for Sinkina, declared the product unworthy of recognition and adopted the following report, which was sent to the manufacturers:

> No experimental evidence regarding the therapeutic value has been submitted. The clinical evidence is scant and not of such character as to deserve much consideration, no sufficient precautions having been adopted to avoid wrong conclusions. Judging from the evidence at hand the preparation is simply a dilute sugar-alcohol-water solution containing a little oil of cumin—Roman caraway. It is highly improbable that such a liquid would have the therapeutic effects claimed for it by the Metropolitan Pharmacal Company. In view of the improbable claims made for Sinkina, and the failure to substantiate them by suitable evidence, it is recommended that the preparation be refused recognition without at this time considering the claims made in regard to the identity and amount of the drug claimed to be the essential constituent.

In spite of its rejection Sinkina was persistently advertised. It was thought advisable, therefore, to submit the preparation to clinical tests. This was done and the results are given in the following report:

THE CLINICAL REPORT

The following quotations indicate the claims made for this preparation:

> "In malarial conditions there is nothing that acts so promptly and efficaciously as Sinkina. Sinkina destroys radically every trace of the parasite in the blood from the time of its first appearance, builds up the damaged corpuscles, revitalizes the system, and completely eliminates every trace of the disease. Sinkina is deservedly termed the *Specific* for Malaria."

These claims were supported by testimonials which usually gave no indication of a demonstration of the presence or absence of malarial plasmodia in the blood. The following is an example showing the character of most of the evidence presented by the manufacturers:

> "Three weeks ago I prescribed Sinkina for a negro man 40 years of age suffering from a double tertian malarial infection having a chill every afternoon for four consecutive days. He came to my office about 8 a. m. and was due to have a chill about 6 p. m. I gave him the sample of Sinkina and directed him to take a tablespoonful at once also at noon and again at 4 p. m., and to continue taking it in same size dose three times a day till he had taken it all. He reported to me in a week from that date and told me he was feeling fine and that he hadn't had any more chills. The patient up to this time is apparently cured."

As the claims were supported by a few testimonials purporting to be based on exact investigations, the Council submitted the preparation to careful laboratory and clinical tests. For this investigation the Council was fortunate in securing the help of physicians actively engaged in the study of malaria.

Experiments were made *in vitro* with the preparation; 1 ounce of Sinkina was used, and its action was compared with that of 10 grains of quinin sulphate. When these were added to cultures of malarial plasmodia in proportion corresponding to 1 ounce of Sinkina or 10 grains of quinin sulphate for a 150-pound man, the quinin was found to be unfailingly antagonistic to the malarial organism, the drug prevented the segmentation of the organism and finally killed it in about thirty-six hours. The Sinkina did not kill the parasite after seventy-two hours of continued action, and the parasites segmented in the presence of it just as actively as they did in the control.

The investigator was furnished with two sets of preparations in plain prescription bottles so as to avoid all influence of the personal equation. One set consisted of Sinkina, the other of a mixture of alcohol, sugar and water with some oil of cumin. The investigator reported that, so far as the tests on the cultures of malarial plasmodia were concerned, he could not determine any difference in the results obtained with the oil of cumin preparation, made in the laboratory of the Association, and those obtained with the Sinkina of the Metropolitan Pharmacal Company. Clinical trials were made by three independent investigators. Two of them received the two sets of preparations described.

FIRST INVESTIGATION

The first investigator treated two cases with Sinkina: one was of the ordinary estivo-autumnal type and the other an ordinary tertian.

Cases 1 and 2.—A good many schizonts were present in the blood of each patient forty-eight hours after the administration of Sinkina. In the instance of the case of tertian the patient had his chill forty-eight hours after the medicine had been started. As the Sinkina failed to produce any effect the patients were then put on quinin to stop the disease.

Case 3.—The patient had taken 10 grains of quinin on the day on which the experiment was begun. He had the tertian form of the disease, and plasmodia were quite numerous at the beginning. The quinin was discontinued and Sinkina was given in doses of 1 ounce three times a day. The day following the administration of 10 grains of quinin and 1 ounce of Sinkina, no parasites could be found in the blood. The Sinkina was continued in the doses mentioned. On the seventh day the patient had another chill, and a great many parasites were found in his blood. The Sinkina was discontinued and the patient was at once relieved by quinin.

This investigator gives it as his opinion, based on these observations, that the preparation (Sinkina) is absolutely worthless in the treatment of malaria, and he does not think it necessary to make any further experiments with it.

SECOND INVESTIGATION

The second investigator treated two cases of tertian malarial fever with these preparations until it was satisfactorily proved that the drug was having no effect on the presence of the parasites in the blood, when he began the administration of quinin.

Case 4.—After the use of the remedies for one week the investigator still found young rings half-grown and gametes present in the blood. Apparently there was a relative increase in the number of parasites. He then began the administration of quinin. Blood-smears taken the next day after 40 grains of quinin had been taken showed one parasite after eighteen minutes' search of one slide, and two after thirty minutes' search of a second slide. At the end of a week's treatment the patient was discharged recovered. The blood examination of two slides was negative.

Case 5.—This was a case of tertian malaria. After treatment for five days with Sinkina the blood still showed tertian parasites with increase in the size of the spleen, and the preparation was without effect on the clinical course of the disease. Quinin was then begun, and the blood examination became negative at the end of three days.

The investigator concludes that the preparations furnished him were absolutely worthless in the treatment of two cases of the tertian form of malarial fever, and that these solutions had no effect on the presence of the parasites in the peripheral circulation. In a case of quartan malaria, both of the preparations (cumin oil mixture and Sinkina), sent by the Association Laboratory, were without effect on the plasmodia in the blood. This investigator employed the solution made by the Association Laboratory (cumin oil mixture) as well as Sinkina, and was unable to note any differences between them.

THIRD INVESTIGATION

The third investigator began the trial of Sinkina at the instance of the manufacturers, and used it in three cases, two of them being benign tertian malaria and one case of mixed infection (benign tertian and estivo-autumnal).

Case 6.—This was one of the cases of benign tertian malaria. The patient gave a clinical history of malaria with chills occurring on alternate days for a little over a week. There was an immediate cessation of all clinical symptoms, and three days after the patient had been on ½ ounce of Sinkina three times daily there was no evidence of any plasmodia in his blood; his additional treatment consisted of 5 grains of calomel the evening of the first day with a saline the next morning. Before the patient was put on treatment, numerous parasites of both the asexual and sexual forms were observed. The patient remained in bed for a few days, and then returned to work. A week later he was again taken ill with a return of all of his previous clinical symptoms.

Case 7.—This case was one of mixed infection (benign tertian and estivo-autumnal). The patient had a clinical history of malaria dating back two weeks, with a maximum temperature of 104 on admission. Tertian rings, estivo-autumnal rings and crescents were found in the blood. The patient was placed in bed, given thorough eliminating treatment, and ½ ounce of Sinkina was administered four times daily. His clinical symptoms ran on for two days with no change, and there was no difficulty in finding the plasmodia in blood-smears, which were taken twice daily. The dose was then doubled and at the end of four days more there was no change in either his clinical symptoms or the blood-findings. The patient was then placed on 10 grains of quinin sulphate with 15 drops of diluted hydrochloric acid three times daily, to which he responded in less than forty-eight hours and made an uneventful recovery.

Case 8.—This was the other case of benign tertian malaria. The patient had chills every other day while on the treatment, and laboratory diagnosis confirmed the clinical findings. Experimental treatment was carried on for four days, with a negative result.

The investigator calls attention to the fact that the first case in which improvement resulted does not show any necessary connection with the Sinkina administered, for many cases of benign tertian will clear up in just as short a time under any line of treatment, while practically all will eventually do so. This investigator later reported another case and transmitted a clinical chart.

Case 9.—This patient was admitted to the hospital, Dec. 30, 1912, with a history of having had malaria for some weeks. The diagnosis was confirmed by a blood examination. He was then carried for four days without treatment other than rest in bed and a liquid diet. His symptoms subsided by the third day. On the fourth day a count of the parasites was made which showed that there were 1,160 asexual parasites and 260 sexual forms to every thousand leukocytes. The following day he was placed on Sinkina, 1 ounce three times daily. There was exacerbation of symptoms on the following day, which gradually increased until the fourth day, remaining about stationary for a day or so. The fifth day after the patient had been placed on Sinkina, another count of the parasites showed 5,600 asexual parasites and 300 sexual forms to the thousand leukocytes, this being an increase of 4,440 asexual forms and forty sexual forms to every thousand leukocytes. With the second count of parasites the dose of Sinkina was increased to 2 ounces every four hours, the patient being kept on this until January 14, without result. He was then placed on quinin, with a complete reduction of the temperature to normal and the disappearance of the parasites from the blood.

The investigator also reported a case of benign tertian malaria.

Case 10.—This was in a child of 8 years which was treated by the investigator's confrère and gave similar negative results. Blood examination showed numerous parasites. The child was placed on 1 ounce of Sinkina three times a day and kept on it for two weeks. The clinical picture remained unaltered, and parasites could be detected in numbers whenever examinations were conducted. A gradually increasing enlargement of the spleen was also noted. At the end of two weeks quinin was substituted, and the child went on to a rapid and uneventful recovery.

This investigator also concludes that the claim put forth by the Metropolitan Pharmacal Company that Sinkina is a specific in the treatment of the malarial fevers is entirely without foundation, and that the firm will be unable to demonstrate to the contrary.

These investigations demonstrate that Sinkina is not a specific against malaria, and that it has no more effect than a mixture of oil of cumin, sugar, alcohol and water. They further show the fallacy, first, of concluding from a temporary cessation of the symptoms in malaria that the disease has been cured and, second, of ascribing such temporary improvement to the influence of a remedy which has no known effect on the malarial organism.

Correspondence

Creeping Eruption

To the Editor:—I have noted the publication of reports of two cases of creeping eruption (The Journal, July 26, 1913, p. 247), by Dr. Gustave L. Rudell, in one of which, in August, 1912, he was able to recover the larva. In view of the fact, as stated therein, that recovery of the parasite producing this lesion is exceedingly rare, only two investigators having previously reported finding it, it might be of interest to report that in August, 1910, I succeeded in recovering two of these organisms from such a case while in hospital work in Philadelphia. I had not reported the case prior to this writing, since that part of the limited literature on the subject which had come under my observation had not before impressed me with the fact that the demonstration of this organism in connection with these cases was of such rare occurrence as is apparently true.

My notes show that both parasites found by me were practically the same as to shape, size and body markings as a specimen represented in a drawing after Sokolow, in Pusey's text-book—which was reproduced in The Journal of July 26—with the single exception that ring markings of the body in these specimens were not fully visible except near the head; there was a general motility of the body of a slight degree. The two larvae in question were recovered from the right forearm as small black dots, barely visible to the naked eye, and embedded in the cuticle at points of intense itching.

In this case it was notable that there was practically no difficulty encountered in finding and extracting the larvae, which were picked from the skin along with small scale-like particles of cuticle by the crude method of using the nails of thumb and forefinger, and in these two instances the small mass thus obtained was placed on a slide moistened with water for microscopic examination; patient himself in my presence later picked a third one from this forearm which was not examined microscopically. It was likewise worthy of note that there was no eruption of a distinctly "creeping" nature in this case, but at each of the three isolated points of itching, which alone drew patient's attention to the condition, there was a small erythematous area (no doubt intensified by scratching the parts) in the center of which was a slight scaly puckering of the epidermis containing the black dot.

Patient stated that he had been conscious of itching for only a few hours before I saw him and later informed me that he was aware of no further symptom of this kind after removal of the larvae. I might further add that he had just previously spent several days at the seashore, frequently in surf-bathing, at which time the larvae were probably deposited on his forearm.

Thomas H. Cates, M.D., Little Rock, Ark.

Lactobacilline—A Reply

To the Editor:—May we call your attention to what is doubtless an unintentional injustice done our product, Lactobacilline Liquide, in the Queries and Minor Notes Department of The Journal, Aug. 23, 1913, p. 618? In your note you refer to an article by Professor Heinemann, dated Jan. 30, 1909, stating that yeasts were found in the product of the Franco-American Ferment Company as sold in the form of powder and tablets and that "Sewerin also failed to find *B. bulgaricus* in Lactobacilline."

The Lactobacilline preparations examined by Professor Heinemann were imported and were foreign products obtained previous to the time when the Ferment Company of New York manufactured Lactobacilline. The Lactobacilline referred to by Sewerin was examined by him in Russia and was not manufactured in America. His report was published in the *Centralblatt für Bakteriologie*, November, 1908, and was merely referred to in The Journal, Jan. 27, 1912. Evidently, therefore, the criticisms of Heinemann and Sewerin do not apply to the Lactobacilline products which we sell.

As to the query propounded by your correspondent regarding Professor Metchnikoff's supervision of the Franco-American Ferment Company's preparations, we wish to give the following information: Once a month samples of all Lactobacilline products made in this country are bought at random in the open market by an independent law firm which acts as attorney for Professor Metchnikoff and La Societé Le Ferment. These are sent to Paris for examination. If they are not found to conform to Professor Metchnikoff's scientific requirements, *ipso facto*, we lose the right to use his name in connection with the products.

When under the authorization of Professor Metchnikoff we first put the Lactobacilline products on the American market, the therapeutic efficiency of the *Bacillus bulgaricus* in the various forms of auto-intoxication was but little known to the profession and we felt compelled to enclose printed matter in our packages. This, we were led to believe, made our products unacceptable to the Council on Pharmacy and Chemistry under its rules. It was for this reason solely that the Lactobacilline products have not heretofore been submitted to the Council and we wish to take this opportunity of stating that steps have been taken to submit these products to the Council on Pharmacy and Chemistry in the belief that they will be found acceptable for inclusion in New and Nonofficial Remedies.

The Franco-American Ferment Co.,
by Joseph C. Richard, Vice-President.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

STATES IN WHICH GOVERNMENT PHYSICIANS MAY REGISTER WITHOUT EXAMINATION

To the Editor:—In what states, if any, are medical officers of the United States Army, Navy and Public Health Service (on the active list, retired or resigned) allowed to register, without taking the regular state board examination? Please omit my name in answering.

E. M. D.

Answer.—The following states have taken legislative action in this regard:

1. Alabama grants a certificate to practice to any such officer on the active list, provided he can produce evidence as to his still being in the service.
2. California allows the medical officers of the Army and Navy, whether on the active list, retired or resigned, to practice in that state on a proper showing that they are or were duly commissioned, and on paying a fee of $50.
3. Illinois permits the State Board of Health to use its discretion in issuing licenses without requiring an examination to any physician who is a graduate of a medical college and who

has passed an examination before the United States Army, Navy or Public Health Service.

4. North Dakota allows the experience which any one has gained in the Army, Navy or Public Health Service to be given due consideration. The board may in its discretion license such officers without an examination on paying a fee of $25 and producing proper credentials as to their service, etc.

5. Texas permits surgeons and such officers of the United States Army, Navy or Public Health Service to engage in private practice if a license to do so is first obtained from the board.

The majority of states, it would seem, permit such officers to practice only in the line of their official duties. In a few states the language of the statutes might be construed to imply that government medical officers may practice without being first licensed. An example of this is Iowa. Its statute says that the act is not to apply to surgeons of the United State Army, Navy and Public Health Service. It does not say that this is simply in the line of their official duties. It may therefore be inferred that such officers may practice privately. Kentucky, Louisiana, Maryland, Tennessee and Wisconsin have similar language in their laws. The New York statute exempts such officers "while so commissioned." This would seem to imply that such officers may practice privately while still commissioned.

WEICHARDTS' ANTIKENATOXIN — BAUME ANALGESIQUE BENGUE

To the Editor:—1. What is Weichardts' Antikenatoxin? A paper was read on the use of this substance at the recent congress in Buffalo.

2. What is the composition of Baume Analgesique Bengue? Is there any official preparation of similar constituents?

S. T. A., New York.

ANSWER.—1. We have no information in regard to Weichardts' Antikenatoxin.

2. Analyzed by the British Medical Association this "patent-medicine"-"ethical-proprietary" was found to have the following composition (THE JOURNAL A. M. A., Dec. 14, 1912, p. 2173):

Menthol	18 per cent.
Methyl salicylate	20 per cent.
Lanolin, anhydrous	54 per cent.
A fat, apparently lard	8 per cent.

No similar preparation is described in the United States Pharmacopeia or in the National Formulary, but the British Pharmaceutical Codex, gives tne following:

Unguentum methylis salicylatis compositum B.P.C.

Methyl salicylate, by weight	50.00	(10 ounces)
Menthol	10.00	(2 ounces)
Eucalyptol, by weight	2.50	(¼ ounce)
Oil of cajuput, by weight	2.50	(¼ ounce)
White beeswax	17.50	(3¾ ounces)
Hydrous wool-fat	17.50	(3¾ ounces)

Mix the wool-fat with the melted beeswax, gradually incorporate the menthol and liquids, previously mixed by trituration, and stir until cold.

SEASHORE SANATORIUM

A correspondent asks us for the address of "one or more sanatoriums located at or near the seashore, either on the Eastern or Southern coast." We shall be glad to receive information for our correspondent regarding such sanatoriums.

OXYOLINE AND OZONE MACHINES

To the Editor:—What about the Oxyoline (ozone) machine that a number of our doctors are using? I had always supposed that it was a fad on a par with the nebulizer and other such stuff that we have seen come and go. Lots of it is now piled up in physicians' offices all over the country. An agent for the Oxyoline outfit was here yesterday to see me, however (and I don't mind telling you that he is about as smooth an article as ever "came down the pike"), and showed me letters from some of our best men (some of them members of our state society and of the American Medical Association), who make some very big statements in regard to the curative properties of ozone. If there has been anything published in regard to these people in THE JOURNAL, please tell me where to find it. Also anything that you know about this outfit. On its face this proposition doesn't look good. Any advice will be appreciated.

F. P. STEVENSON, M.D., Aurora, Mo.

ANSWER.—The subject of ozone machines is dealt with both in the editorial and in the original article departments of this issue. The "Oxyoline" machine was discussed in THE JOURNAL, Nov. 11, 1911, page 1629. The concern which exploits it has made claims that are not only unscientific but absolutely fraudulent. The apparatus itself is being used in various places as an accessory to quackery. The main points emphasized by the manufacturers of the Oxyoline machine are not those of therapeutic efficiency of the device, but the money-making possibilities in it.

PRACTICAL NEWSPAPER COOPERATION

The value of intelligent cooperation on the part of the newspapers in saving life is well shown by a letter and two editorials, recently received from Mr. William L. Geppert, editor of the *Daily Telegram*, of Clarksburg, W. Va. Mr. Geppert, as a public-spirited newspaper man, was impressed with the need of wide-spread publicity of editorials in recent issues of THE JOURNAL on "Suicide with Bichlorid of Mercury." These editorials, distributed by the Association Press Bureau to the newspapers, have been widely copied. Mr. Geppert, however, not only reprinted the editorials, for the information of his readers, but also suggested a practical way in which the newspapers can cooperate, that is, by making it an inflexible rule to omit from newspapers all mention of the means by which self-destruction was accomplished. Mr. Geppert's editorials are worthy of reproduction, as an illustration of the value of newspapers in the campaign for better health conditions.

The first editorial was entitled:

"PROMOTING DEATH

"For the sake of despondent and melancholic humanity, the *Telegram* desires to 'call down' a newspaper correspondent of Fairmont for telegraphing to various newspapers the kind of poison that was swallowed by a child there a day or two ago by mistake and that resulted in the child's death; and also the name of the poison taken by a man there last evening with suicidal intent. The *Telegram* also desires to condemn the Wheeling newspapers that chronicled the names of the poisons in headlines over the same items, and other newspapers that published the items without eliminating the name of the poison. And, further, the *Telegram* desires to lay down a rule to be followed by newspapers in publishing news items of suicides, accidental deaths and other like tragedies caused by poisons, namely, to eliminate the name of the poison.

"Not so very long ago, as will be readily recalled, a Georgia banker died of a poison taken in mistake; and the name and the nature of the poison were heralded from one end of the land to the other with what was declared to be not altogether an accurate account of its effects. Immediately thereafter a wide-spread series of suicides from this same poison occurred throughout the country; and cause and effect were so obvious as to lead THE JOURNAL of the American Medical Association to enter a vigorous protest against the publication of such cases altogether.

"While it is probably too soon to expect any notable decrease in the endless publication of ordinary crimes and tragedies with which newspapers are half filled nowadays to no good purpose, it is not too soon to begin a campaign against the unwitting advertisement of poisoning methods—against a promotion of death and destruction that would scare the consciences of many persons when brought to realize its actual significance. Accounts of suicides, especially, should be so judiciously edited as to offset the direful effects resulting through mental suggestion on weak, ignorant, despondent and afflicted persons.

"In regard to the poisoning cases at Fairmont, commendation is due the Associated Press for flatly refusing to carry the names of the poisons in its stories of the fatalities."

In the second editorial, the editor makes an exception to his own rule, for very good reasons. He says, under the heading:

"AN AGONIZING DEATH

"It is a rule of the *Telegram*, as well as other respectable journals and great news-dispensing association like the Associated Press, to refrain from publishing the name of a poison in connection with reports of suicides and it regards a violation of the rule as reprehensible journalism. It is unnecessary to repeat in detail the *Telegram's* reason for this, as it is perfectly obvious what effect such suggestion can have and daily does have on the minds of melancholic persons.

"In an earnest desire, however, to do what it can to offset the recent blunders of many newspapers in advertising a certain poison for suicide, or, in other words, promoting self-destruction, the rule will be here overstepped, but in a general way. A mistaken belief prevails that poisoning by bichlorid of mercury is an easy means of taking oneself off. The contrary, however, is the case as the poison is deadly, insidious, productive of great suffering, and so slow-working that the agonies of death are long drawn out. As a means of death bichlorid of mercury is the worst that can be used. Let The Journal of the American Medical Association affirm this in more authoritative words."

The rest of the editorial consists of a quotation from the editorial in The Journal.

SURGICAL INSTRUMENTS UNDER THE TARIFF BILL

In The Journal for May 3, 1913, p. 1382, the tariff rates on surgical instruments and the like under the present law were compared with the rates in H. R. 3321, as it was introduced into the House of Representatives. This analysis of the two measures showed a reduction from 45 per cent. ad valorem on surgical and dental instruments, or parts thereof, as are included in Paragraph 199 of the present law, to 25 per cent. ad valorem, as in Paragraph 169 of the Underwood bill. And this rate has been even further reduced by the finance committee of the Senate to 20 per cent. ad valorem. When Paragraph 130 was being discussed in the Senate, Senator Smoot moved to amend this at line 17, after the word "ad valorem," by inserting "surgical and dental instruments, or parts thereof, 40 per cent. ad valorem."

The amendment was proposed at the suggestion of the instrument manufacturers of this country, who, as Senator Smoot said, assert that even under the present 45 per cent. rate, fully 80 per cent. of such goods are imported from abroad, and that only about 20 per cent. are manufactured in this country. A reduction of 25 per cent., it was argued, would be extremely detrimental to our manufacturers. The proposed amendment was rejected. Senator Stone, however, promised to give the matter further consideration in the finance committee.

One View of "Friedmann Serum."—After having carefully studied all reports coming to hand through the medium of an extensive exchange list of first-class medical journals, our deliberate judgment is that the so-called "Friedmann serum" for the treatment of tuberculosis is either a fraud or half-baked scientific product, propagated solely for profit. It is destined not only to prove a source of exceedingly and inexcusably disastrous disappointment to the victims who have been attracted through their well-known credulity and the magnificent newspaper exploitation Friedmann has secured for his "cure," but a seriously dangerous remedy as well.

It is needless to say that the State Medical Association of Texas will not sanction the use of any secret remedy, particularly one deemed to be potentially dangerous and coming under such a cloud of disrepute as does the Friedmann serum. Our answer is that when the United States government issues a license to cover the manufacture of this serum, the State Health Department sanctions its use in the state and the Council on Pharmacy and Chemistry of the American Medical Association admits it to the New and Nonofficial Remedies, then, and not until then, will we sanction its use in this state. This is not an unreasonable stand to take because none of the requirements are impossible or difficult to meet. In view of the importance of the subject and the well-known ability and integrity of the physicians composing these bodies, it is strange that those who are exploiting this remedy, if they are honest in their belief in its efficacy, will not submit it for their approval.—*Texas State Jour. Med.*, September, 1913.

Wyoming: State House, Cheyenne, October 15. Sec., Dr. J. B. Tyrrell, Laramie.

PSYCHOLOGY AND THE MEDICAL SCHOOL

SUMMARY OF THE REPORT OF THE COMMITTEE ON PSYCHOLOGY AND MEDICAL EDUCATION OF THE AMERICAN PSYCHOLOGICAL ASSOCIATION *

Following the symposium on psychology and medical education[1] before the American Psychological Association in December, 1911, a committee was appointed to investigate and to cooperate with other bodies interested in this matter. The first part of the investigations of the committee forms the basis of the present report.[2]

The committee sent to all the known medical schools in the United States and Canada inquiries regarding the advisability of including psychology as a required subject for medical students. There were 102 American medical colleges from which answers might have been expected. Answers were received from 71, over two-thirds of the presumably active medical schools in this country. No answers were received from the eight Canadian medical colleges. In general the fullest answers were received from the Class A+ medical colleges, while on the other hand, with but few exceptions, the answers from the medical colleges in Classes B and C were most unsatisfactory as regards completeness.

The committee requested information along five lines. The special questions which were asked are given below. It will be noted that matters regarding which inquiries were made were not entirely or strictly psychologic. The inquiries were made broad because the general medical conception of psychology is not that of the professional psychologist or psychiatrist, as some of the answers plainly showed.

---

* Members of the committee: Shepherd Ivory Franz, scientific director and psychologist, Government Hospital for the Insane, and professor of physiology, George Washington University Medical School, chairman; E. E. Southard, professor of neuropathology, Harvard Medical School, and director of the psychopathic department of the Boston State Hospital, and J. B. Watson, professor of psychology and director of the psychologic laboratory, Johns Hopkins University. The full report will appear in *Science*, 1913.

[1] Franz, Shepherd I.: The Present Status of Psychology in Medical Education and Practice, The Journal A. M. A., March 30, 1912, p. 909.

[2] At the present date two other associations have appointed committees with practically the same duties, that is, the American Psychopathological Association, at their meeting in May, 1913, and the American Medico-Psychological Association, at their meeting in June, 1913.

"1. What amounts of time and what proportions of the courses in anatomy (including histology), physiology and pathology are devoted to the nervous system?"

The individual answers to this question were on the whole unsatisfactory. Many of the colleges reported the numbers of hours without the percentages, others gave the percentages without the numbers of hours, and in only a comparatively few instances was the information complete. A tabulation of the answers, so far as this could be done, is given in Table 1.

TABLE 1.—ANSWERS RECEIVED FROM MEDICAL COLLEGES

	Hours	No. of Answers	Percentages	No. of Answers
Anatomy	123	26	17.5	17
Physiology	71	31	22.5	22
Pathology	30	22	12.3	18

From these averages the individual answers varied greatly. In anatomy there were reported 54, 55 and 60 hours by three schools, and 185, 192 and 246 hours by others. In physiology, two schools reported 18 and 20 hours, respectively, and two others 139 and 150, respectively. In pathology, the smallest amount of time was 5 hours, the greatest 60 hours. These variations may indicate differences in conception of different teachers of the relative importance of the nervous system, or, what appears to us likely in some cases, misunderstanding of the terms used. It is not reasonable to suppose that any school gives only fifty-four hours for dissection, demonstration and lectures on the nervous system, or eighteen hours to its physiology. In two widely used text-books of physiology the nervous system is given, respectively, 32 and 39.5 per cent. of the total space. It is probable that the term "nervous system" was, in a number of cases, used by our correspondents to denote only the central nervous system, and was not understood to include such obvious parts as the peripheral nerves and the organs of special sense. It is interesting and important, however, to note that, even with these probable underestimations, the total time assigned to the study of the nervous system averages about 10 per cent. of the total time of the first two years of the medical curriculum. If the question had specified "nervous system, including central and peripheral, and organs of special sense" it seems likely that most of the lower estimates would have been increased in anatomy and physiology so that nearly 15 per cent. of the time of the first two years would be shown to be devoted to the nervous system.

The committee believes that while it may be possible to teach anatomy, physiology and pathology without reference to psychologic matters, in practice this is rarely done. In considering the present status of psychology in the medical curriculum, account should therefore be taken of the inclusion in anatomy of a modicum of psychology, and in dealing with such matters as sensation and perception in the courses in physiology we must remember there is no strict separation of psychologic facts and theories from those of a physiologic nature.

"2. How far do the third (or fourth) year courses in nervous and mental diseases take up the biologic sides of neurology and psychiatry?"

From the answers received it is apparent that in a large proportion of our medical schools, neurology and psychiatry are taught as clinical subjects—diseases are described, differential diagnostic signs are discussed and methods of treatment are suggested. The broader aspects of these subjects are apparently not even hinted at in many schools, although a superficial reading of many of the answers might lead to the opposite conclusion.

"3. Are there elective or graduate courses in medicine which deal with the relations of neurology, psychiatry and psychology, and how much time is given to them?"

Only two schools out of sixty which answered this question replied in the affirmative. It is apparent that students and graduates in medicine who incline toward practice in diseases of the mind and nervous system have few or no opportunities in the medical schools of this country to acquire a broader acquaintance with the subjects of neurology and psychiatry than the clinical courses offer, but must turn to some other source. At times, courses have been given in connection with psychiatric institutes or hospitals for the insane to fit their own appointees for the work they may be expected to perform. With the exception of an apprenticeship in a hospital for the insane, and this is not always adequate, there is at present no possible means of getting an adequate conception of and training for dealing with the mass of nervous and mental disorders which is encountered in general practice. When it is realized that the proportion of insanity is greater than 1:300 of the general population, it is a matter for wonder that the medical schools do not offer adequate means for the acquirement of knowledge along these lines. It is not an exaggeration to say that the courses on insanity and neurology in medical schools are inadequate in time and usually quite unfit in character to prepare the student of medicine for this difficult part of his practice.

"4. Is there any correlation or cooperation between the department of psychology in the academic department and the department of neurology and psychiatry in the medical school?"

Three schools failed to answer this question; three others did not answer it because they were two-year schools, but their failure to answer for this reason indicated plainly that there was no cooperation or correlation between the medical work and the department of psychology in the college of arts and sciences. Eighteen other schools reported that they had no academic connections; thirty-three definitely reported no cooperation; one gave an unqualified affirmative answer and the remaining thirteen answered with more than a brief affirmation by giving indications of the character of the cooperation. Of the fifty-two schools which have affiliations, close or remote, with academic departments, only two-sevenths report any form of correlation or cooperation with the department of psychology, but a careful reading of the answers shows that not more than half of these have any definite form of cooperation or correlation. At the most the replies show that in some institutions academic students who are interested in psychology may attend certain courses in the medical school, and that in other institutions medical students are advised to take courses in psychology. It may be concluded that in this respect there is more promise than accomplishment.

"5. In view of the increasing realization of the importance of the mental factor in medicine, is it your opinion that (a) it would be advisable to have given to the students special instruction in psychology, and if so, (b) at what stage of the medical course would this course be best given?"

Only four of the seventy-one medical schools failed to answer the first part of this question. The numbers and percentages of the different replies are as follows: Fifty affirmative, or 75 per cent.; seven negative, or 10 per cent.; ten qualified affirmative and negative, 15 per cent. In addition it is worthy of note that eleven medical schools have already introduced (or plan to introduce next year) psychology into the curriculum or require it for entrance, and one school advises students to take a course in psychology in the preparatory premedical years.

Of the fifty schools which indicated their belief that psychology should be introduced into the medical curriculum, forty-seven have also indicated the position such work should occupy. Twenty-seven of these schools advise that it be placed in the premedical preparatory years or in the first two years of the medical course, and of this number twelve refer, explicitly or by implication, to the dependence of psychology on the facts of anatomy and physiology, and advise its introduction at a time when the courses in the anatomy and physiology of the nervous system are being given or after they have been completed. Although admitting its value, four schools would dismiss psychology by including it as a required course in the premedical years. The other eleven schools advise that a second course be given during the third or fourth years in addition to the requirement of the first years of the medical work. They would divide the instruction in psychology into two portions, the first to be offered to students during the first part (including the premedical years) of the medical course, the second during the last two years of the curriculum. Another school receiving only college graduates, who usually have an academic course in psychology, also plans to have a course in psychopathology in the later years. Twenty schools stated that psychology should be given in the final years, most of these insisting that its place was a part of, or as a special preparation for, the work in nervous and mental diseases.

It may be urged that the views expressed are those of medical men especially interested in psychology, that is, psychiatrists and neurologists. All inquiries of the committee were directed to deans or secretaries of the schools, and only nineteen of the answers contained quotations or opinions from professors of neurology or psychiatry. The medical specialties of our correspondents, so far as they could be learned, ranged over the whole field of medicine. The decisively negative answers to our fifth question were received from five professors of nervous and mental diseases, one of anatomy and one administrative officer; the doubtful answers were received from two professors of nervous and mental diseases, two of anatomy, one each of physiology, medicine and pathology, and three administrative officers; the positive answers were received from thirteen professors of nervous and mental diseases, five of anatomy, three of physiology, three of pathology, ten of medicine, one of surgery, one of hygiene and fourteen administrative officers whose special medical interests are unknown. If all the answers from professors of nervous and mental diseases be omitted because of possible professional bias, the percentage of replies in favor of the introduction of psychology into the period of medical training is about the same as the general percentage.

From the facts which the committee has been able to gather the following conclusions have been drawn:

1. It appears to be the preponderating opinion that some instruction in psychology is necessary so that students may understand the mental side of their patients, not only of those who are insane but also of many who are never sent to institutions for nervous or mental diseases.

2. In those schools which require one or two years of college work part of the premedical preparation should be devoted to general psychology, or in lieu thereof, a course should be given, preferably in the second year, after the general work in anatomy and physiology of the nervous system has been completed. A briefer course following the physiology of the nervous system would be more desirable than a course in the premedical years. If the earlier course be more extensive and devotes sufficient time to the functions of the nervous system, the advantage of the later course would be counterbalanced.

3. It is the belief of most of the best schools that a second course in psychology should precede the course in clinical psychiatry and neurology. This course should be more practical and should deal especially with abnormal mental processes and with the application of psychologic principles and facts to medical topics. This course should deal chiefly with psychopathology, but it should not be permitted to develop, or degenerate, into a course in psychiatry, neurology or psychotherapeutics. Clinical material should be the basis of the course, but it should not assume the functions of the courses in psychiatry and neurology.

4. Both courses in psychology should be given by competent medical men, although there are at present few medical men who have had sufficient training or have sufficient interest in psychology to warrant their appointment to initiate such work. It seems best, therefore, to recommend that these courses be given jointly and cooperatively by the departments of psychology and psychiatry or neurology.

5. The content of the course or courses in psychology should be the object of careful consideration by representatives or fessors of the departments of physiology, psychiatry, psy- gy and neurology. The first course in psychology, as uctory to the study of medicine, should be a general dealing largely with general psychologic facts, stand- methods, but constant reference should be made ical problems which may be solved by means of the psychologic methods and facts which are discussed. The advanced courses, however, should be practical and should deal with actual medical facts as much as possible. Both courses in psychology should be laboratory or experimental so far as possible, that the student may become personally acquainted with the methods and with the general nature of psychologic experimentation, rather than obtain his knowledge from text-books.

6. More extensive and intensive cooperation between psychologists and physicians is desirable. From the psychologist's standpoint the psychology of medical men is crude; from the medical standpoint the pathology and physiology of the psychologist are out of date. Since both classes have many common interests the knowledge of psychologists should be utilized by physicians, and in turn the experience of more physicians might be made available for the advancement of psychology and psychopathology.

Book Notices

Studies in Small-Pox and Vaccination. By William Hanna, M.A., M.D., D.P.H., Assistant Medical Officer of Health of the Port of Liverpool. Cloth. Price, $3 net. Pp. 52, with 25 illustrations. New York: William Wood & Co., 1913.

Dr. Hanna's book contains the results of his experience as health officer for the port of Liverpool. It consists of three parts: (1) a statistical study of 1,163 cases of small-pox, with special reference to the influence of vaccination in modifying the disease; (2) an analysis of 943 cases of small-pox (with primary vaccination) in relation to scar-area and severity of disease; (3) observations on the interaction of small-pox and vaccination. The study is an exhaustive one and the book is well illustrated with excellent photographs, well printed on good paper.

Hanna draws the conclusions from the first part that the small-pox mortality in the unvaccinated ranges from 25 to 40 per cent. and in the vaccinated is about 3 per cent.; that in the unvaccinated, those at the extremes of life, mainly children under 10 and old persons, suffer the most, the mortality of these two classes reaching as high as 50 per cent.; that in cases in which vaccination does not prevent small-pox, it modifies it to such a degree of mildness that it may be undetected. The conclusions from the second part are that the scar-area of vaccination has an important bearing on the severity of the disease, the larger the vaccination scar, the milder the attack of small-pox, if contracted. From the third part the conclusion is drawn that protection against small-pox is afforded by vaccination even if performed within three days after infection is contracted. The monograph is carefully and conservatively written, all of the statements being supported by facts and records.

Pathologic Inebriety. Its Causation and Treatment. By J. W. Astley Cooper, Medical Superintendent of Ghyllwood Sanatorium, with Introduction by Sir David Ferrier, M.D., F.R.S. Cloth. Price, $1.50 net. Pp. 151. New York: Paul B. Hoeber, 1913.

It is not to the credit of the medical profession that probably a large majority of its members look on the man suffering from an overdose of alcohol as a "drunk" of the more or less common variety. Whatever may be the cause of the intoxication, or whatever one's attitude toward the questions of personal temperance or general prohibition may be, the person who has taken, either in a long or a short period, an overdose of alcohol in any form is quite as much a subject for proper professional treatment as is the victim of morphin or strychnin poisoning. That the majority of physicians need information and instruction on the treatment of inebriety will be admitted by all who have given the subject serious consideration. Dr. Cooper endeavors to show that any efforts to cure inebriety by punishment are not only mistaken but also useless, and that proper medical treatment with adequate legal control is necessary in handling these cases. The natural forms and causes of pathologic inebriety are considered. The author recognizes three forms, dipsomania, periodic alcoholism and chronic inebriety. Dipsomania he defines as a sudden periodic inebriety caused by an insane impulse to take stimulants to intoxication, irrespective of any immediately preceding alcoholic indulgence. The periodic alcoholic he distinguishes from the dipsomaniac in that as long as the periodic refrains from the use of alcohol he has no desire for it, while the dipsomaniac has the impulse whether he yields to it or not. The complications of inebriety are discussed under the heads of delirium tremens, epilepsy, albuminuria and insomnia. Treatment is considered under prevention, treatment by specific drugs, secret remedies and social remedies such as temperance societies, etc. To one familiar with the facts, the author in his reference to the "Keeley Cure" does not convey the impression of exhaustive investigation. In discussing drug treatment the author pays little attention to any other indication. Little emphasis is placed on the fact well known to every person who has seen any large number of alcoholics that the real drunkard, either periodic or chronic, always stops eating as soon as he begins drinking. The result is that the man who has been on a protracted debauch is not only suffering from alcoholic poisoning, but is also in an acute stage of malnutrition. The atropin and strychnin treatment and the system of treatment devised by Dr. Alexander Lambert of New York are discussed in detail. The book is not a particularly profound or exhaustive discussion of the subject but should be of value in attracting attention to a much-neglected field.

SAFEGUARDING THE SPECIAL SENSES. General Advice Regarding the Use and Preservation of the Eyes, Ears, Nose and Throat. By Henry O. Reik, M.D. Cloth. Price, $0.75 net. Pp. 123, with 4 illustrations. Philadelphia: F. A. Davis Company, 1912.

This is the result of fifteen years of experience in treating diseases of the eye, ear, nose and throat. Reik's experience has convinced him that the public needs more careful instruction as to the protection and preservation of the special senses. In the preface, he says, "The child is not expected to know that snoring generally means obstructed respiration, that recurring attacks of pain in the ear mean an abnormal growth in the nose or throat, or that inability to clearly see the school blackboard, or headaches following study are indications of bad eyes . . . The parents are but little wiser. Disinclination to study, a tendency to 'hook school' or failure to maintain a satisfactory class standard are much more frequently due to poor vision or eye-strain than to original sin." Parents are also negligent regarding their own sense organs. Reik's object is to present in a small volume, at a low price, information for the care of the eye, ear, nose and throat that will enable a reasonably intelligent person to keep these special sense organs healthy. The chapter on the eye includes a discussion of eye-strain, care of the eyes, reading-lights, foreign bodies, common afflictions and subjective sensations.

COMMERCIALIZING PROSTITUTION IN NEW YORK CITY. By George J. Kneeland, with a Supplementary Chapter by Katherine Bement Davis, Superintendent of the New York State Reformatory for Women. Introduction by John D. Rockefeller, Jr., Chairman of the Bureau of Social Hygiene. Cloth. Price, $1.30 net. Pp. 334. New York: The Century Company, 1913.

This report is the most elaborate and exhaustive of any yet issued. While covering much the same ground as the report of the Chicago Vice Commission, the experience of the investigator in preparing the first report is noticeable in the last one. The work in both cities was under the direction of Mr. George J. Kneeland. Three other volumes are planned for the present series, the object of the bureau being to collect, study and publish accurate and reliable information regarding the world-wide character of the traffic in vice. Two volumes will deal with the condition of social morals in the leading cities of Europe and with European police systems. The fourth volume will be based on studies made in different cities of the United States.

The material in the present volume is divided into two parts: first, the information secured and tabulated by Mr. Kneeland of actual conditions in New York City, and, second, a report on 647 women committed from New York City to the State Reformatory for Women. This part of the report is prepared by Katharine B. Davis, superintendent of the reformatory, and is largely based on information furnished by the women themselves. The report confirms the existence, not only in New York City, but also throughout the country, of an elaborately organized business for the exploitation of women by men. Probably the most interesting single fact is that brought out by Miss Davis on the mentality of inmates of the State Reformatory. Of 116 of these women, selected at random, and carefully examined by the Binet test, not one showed the mental development which would be normal for a child of over 12 years, twenty-nine had the mental development of 9-year-old children, forty-four of 10-year-olds and twenty-six of 11-year-old girls. From the entire study, Miss Davis concludes that approximately 30 per cent. of those studied are markedly mentally defective, and that this is an extremely conservative estimate. This fact indicates that prostitution is rather a question of mental development and normal mentality than it is of morals or moral impulses.

This report, with the reports from Chicago, Minneapolis and Cincinnati, form the most comprehensive collection of data on this subject available. The book will be read with deep attention by students of social conditions, and the publication of the three remaining volumes of the series will be awaited with interest.

HANDBOOK OF DISEASES OF THE EAR. For the Use of Students and Practitioners. By Richard Lake, F.R.C.S., Surgeon, Diseases of the Ear, London School of Clinical Medicine. Fourth Edition. Cloth. Price, $3 net. Pp. 287, with 81 illustrations. New York: William Wood & Co., 1912.

This little book contains descriptions of the anatomy and brief discussions of diseases of the ear, more particularly the surgical affections. It might be criticized in that it affords, perhaps, a too meager description of many difficult conditions and operations which the author attempts to present. A book on such an intricate organ as the ear and the hearing apparatus, if it is to be of value to the aural surgeon, should be more complete and extensive; but if intended only for the student and general practitioner, as this handbook purports to be, its brevity would make it amount really to a series of definitions of conditions in the hearing apparatus, many of which are difficult to handle even by the expert, and would not be of much assistance to the student or practitioner. The descriptions are well written, however, and the book is abundantly illustrated with splendid drawings and four colored plates.

A STUDY OF THE BACTERIA WHICH SURVIVE PASTEURIZATION. By S. Henry Ayres, Bacteriologist, and William T. Johnson, Jr., Scientific Assistant, Dairy Division. Paper. Pp. 66. U. S. Department of Agriculture, Bureau of Animal Industry, Bulletin 161.

This pamphlet contains the results of experiments in the Bureau of Animal Industry to determine the survival of bacteria after pasteurization by the methods usually employed, both the flash and the holding process. It contains interesting data as to the effectiveness of pasteurization of milk, and should be a valuable pamphlet for the information of health boards, and for distributers of milk who attempt to pasteurize their product.

UNIVERSITY CONTROL. By J. McKeen Cattell, Professor of Psychology in Columbia University. Cloth. Pp. 484. Price, $3.00 net. The Science Press, Garrison, N. Y.

A plea for academic freedom for the individual professor in the university and a protest against autocratic methods of control. A historical retrospect points out how early universities became famous and influential at times when they enjoyed this freedom and how influence waned when this freedom was lost. The greatness of the universities of Germany and elsewhere during the nineteenth century was when academic freedom and the independence and influence of the professor attained a remarkable supremacy. In comparison with the German universities the author states that "no efficient machine driven by the president of an American university can grind out such flour." A series of two hundred and ninety-nine unsigned letters from professors in various American universities are reproduced, and of this number, two hundred and fifty-three favor a greater faculty control of universities or a representative plan suggested in a previous article by the author, allowing of a greater democracy in university control.

The Practice of Urology. A Surgical Treatise on Genito-Urinary Diseases, Including Syphilis. By Charles H. Chetwood, M.D., LL.D., Professor of Genito-Urinary Surgery, New York Polyclinic. Cloth. Price, $5 net. Pp. 824, with illustrations. New York: William Wood & Co., 1913.

There is no dearth of books on genito-urinary surgery, and another addition to the list is not apt to excite the attention that it may deserve. The author's claim to distinction in the preparation of this book is in the fact that he has aligned the subject-matter as seemed to be most practical and desirable from both a surgical and a clinical aspect, beginning with diagnosis and general technic and following with the various abnormalities and diseases of the different anatomic regions, subdividing the operative surgery in like manner. The characteristic features embodied in this book which give it a modern status are the present local treatment of gonorrhea, the application of serum diagnosis and therapy, advancement in cystoscopic and functional renal diagnosis, and the latest on salvarsan therapy. The author is evidently considerably impressed with the value of the Phylacogens, in which many close clinical observers of wide experience differ from him. There is no reason why a method of treatment, young and unsupported by actual clinical results, should be given a place in a text-book. He is decidedly in favor of treatment by vaccines and serums. Urethroscopy and cystoscopy are well described—better than in most books on genito-urinary surgery. The illustrations supplement the text admirably.

The Pros and Cons of Vivisection. By Dr. Charles Richet, Professor of Physiology in the Faculty of Medicine, Paris. With a Preface by W. D. Halliburton, M.D., LL.D., F.R.S., Professor of Physiology, King's College, London. Cloth. Price, $1. Pp. 136. New York: Charles Scribner's Sons, 1912.

Richet is at the head of the Department of Physiology in the Faculté de médecine de Paris. His discussion of vivisection might, therefore, be considered authoritative. In spite of the amount of existing literature on the subject, this little book will be read with much interest by those concerned in the preservation of freedom of research. It will also help the honest seeker after knowledge on this question to clear, accurate information and expert opinion. It is too much to hope that it will have any influence on the pronounced antivivisectionist, as the necessity for animal experimentation has been proved many times before without any effect on those whose minds are already made up. As the discoverer of serotherapy and a leader in physiologic research for a quarter of a century, Richet can speak with an authority not given to the ordinary scientist. An appendix gives the absolute and relative death-rate from diphtheria in Paris from 1872 to 1905, showing a decrease from eighty to fifteen deaths per hundred thousand after the discovery of antitoxin.

The Report of the Philadelphia Baby-Saving Show. And the Proceedings of the Conference on Infant Hygiene. Paper. Price, $1. Pp. 270, with 61 illustrations. Philadelphia: The Child Hygiene Association, Real Estate Trust Building, 1913.

The educational value to a community of a scientifically arranged and conducted exhibit such as that of the baby-saving show held by the Child Hygiene Association of Philadelphia in 1912 is inestimable. The influence of that exhibit and the conference on infant hygiene held in connection with it extended far beyond the community in which it was held. Similar shows employing portions of the exhibit at Philadelphia were held in various cities through the state, showing the interest created by the Philadelphia show. This beautifully printed report gives in detail, with an abundance of illustrations, the various features of the baby-saving show, together with the papers and discussions at the accompanying conference. It constitutes a valuable record and a guide to other communities in preparing for similar educational exhibits, and its wide circulation would distinctly advance the cause of infant hygiene.

Surgery of the Eye. A Handbook for Students and Practitioners. By Ervin Török, M.D., Surgeon to the New York Ophthalmic and Aural Institute, and Gerald H. Grout, M.D., Assistant Surgeon to the New York Ophthalmic and Aural Institute. Cloth. Price, $4.50 net. Pp. 507, with 612 illustrations. Philadelphia: Lea & Febiger, 1913.

This work well fulfils its mission of providing a small, compact students' hand-book. It is well illustrated with original plates and figures showing the important steps in a given operation.

Photomicrographs of Spirochetes, Entamebas, Plasmodia Trypanosomes, Leishmania, Negri Bodies and Parasitic Helminths. Paper. Pp. 45. War Department, Office of the Surgeon-General. Bulletin No. 1. Washington: Government Printing Office, 1913.

This is a highly interesting and valuable bulletin containing plates of various blood parasites together with a brief description and methods of staining and demonstrating them. An improvement that might be suggested would be the printing of the plates in colors.

Gynecologic Operations. Including Non-Operative Treatment and Minor Gynecology. By Henri Hartmann, Professor of the Faculty of Medicine, Paris. Authorized Translation Under the Author's Supervision by Douglas W. Sibbald, M.B., Ch.B. Cloth. Price, $7 net. Pp. 536, with 422 illustrations. Philadelphia: P. Blakiston's Son & Co., 1913.

Hartmann's views are so well known that it is unnecessary to comment on them. This English translation of his book will be welcomed by those who have accepted his teachings.

Medicolegal

Aid Which One Physician May Request of Another Without Incurring Liability Therefor—Requirements of Professional Courtesy

(Gilday vs. Hennen (N. Y.), 139 N. Y. Supp. 934)

The First Appellate Term of the Supreme Court of New York reverses a judgment recovered by the plaintiff, and dismisses the complaint. The court says that the plaintiff and the defendant were both members of the staff of a hospital in the city of New York. While the defendant was performing an operation on a patient, he desired the plaintiff's aid, and sent a telephone message requesting the plaintiff to come to the hospital to help him out. The plaintiff immediately came to the hospital and went into the private operating room. A woman was on the operating table. Her abdomen was open and she was suffering from a hemorrhage. The defendant said to him: "Doctor, I wish you would finish this operation for me. This woman is bleeding. I can't control it." The plaintiff then finished the operation. The defendant was performing the operation for a fee of $10, and the patient was not strictly a charity patient, although the defendant was paying for the private room. The plaintiff thereafter brought this action to recover the reasonable value of his services.

Ordinarily, of course, when a person requests another to perform services for him, he impliedly agrees to pay the reasonable value of the services rendered at his request. This rule is founded in common sense. Unless the circumstances in which the request is made justify him in the belief that the person requested to perform the services would not expect any compensation, the person requesting the services must reasonably have supposed that his request implied a promise to pay for the services. Such circumstances exist where the relation of the parties is such that the services might well be requested as a matter of personal or professional courtesy or duty.

If, therefore, the plaintiff was entitled to recover on an implied contract to pay for the services rendered, it must be on the theory that there is no professional courtesy or duty requiring a physician to give aid to a brother practitioner associated with him in the same hospital, when the brother practitioner's skill or experience is insufficient to cope successfully with an emergency that has arisen and which may cause disastrous results to a patient under his care. The court is absolutely unwilling to hold that the profession of medicine does not impose such an obligation on its members, nor does it believe that even the plaintiff would seriously contend that the judgment in his favor should be sustained, if it would be sustained only on such a theory.

He urged, however, that this obligation existed only in regard to charity patients in the hospital, and not in regard to private patients in a private room. The distinction which he tried to draw was, in the court's opinion, however, not logical. While a physician is entitled to reasonable compensation for his services from the person benefited, the services which he renders should not be measured by the compensation received. Physicians ordinarily recognize this rule and give the benefit of their skill free to persons who cannot pay for the services rendered, and as a matter of professional courtesy will give reasonable assistance to other physicians. The plaintiff showed that he recognized this rule by joining the staff of a hospital where it was the custom that physicians should treat patients gratis and aid each other in their treatment of public patients.

A physician who claims under an implied contract for his services should show, therefore, that the services were rendered, not as a part of his high professional obligations, or as a matter of professional courtesy, but because he expected to be paid for them. This is the test to be applied in every case where a physician sues on an implied contract. It seems to the court that, where a physician requests the services of another physician to aid him in earning compensation for himself, he is bound to pay for these services; but he has a right to believe that a fellow practitioner in the same hospital will expect no compensation, if his services are sought merely to aid him in an operation from which he himself expects to derive no substantial profit. If the operation had been performed in the public operating room, the plaintiff conceded that he would have been reasonably expected to render the requested aid without compensation; but the true distinction, it seems to the court, was not to be found in the place where the operation was performed, but was to be found in the nature and purpose of the services requested. Since the defendant requested the plaintiff's aid, not for the purpose of earning a fee for himself, but only for the purpose of alleviating suffering or removing an imminent danger, he had a right to expect that these services would be rendered freely and willingly.

Elements of Damage to Physician Compelled to Move from His Old Site

(In re Board of Water Supply (N. Y.), 142 N. Y. Supp. 83)

A special term of the Supreme Court of New York, Ulster County, says that this was a motion on the part of several persons having claims for damages for decrease in the values of their established businesses, because of the taking of lands for the Ashokan Reservoir, etc., to confirm the thirteenth Separate Report of Business Damage Commission No. 1. The city of New York made a counter motion to reject the report. One of the claims was that of a physician. The commissioners took the ground that, as his wife did not choose to charge him anything for the rent of his office and barn, there was no reason why any deduction should be made on such an item in the interest of the city. But the court thinks that, in determining his net earnings, the rental value of such office as he used for his business, in the house, and of the barn should be deducted. The fact, however, that he earned, after the taking of the property where his office was located, nearly or quite as much as he earned before, though proved, did not throw much light on his damage. In place of the patrons evicted by the taking of the land men had come to construct the reservoir and the physician's practice had thus been fictitiously sustained, for when the work was completed his old patrons and his new ones would both have gone. Thus the decrease in the value of his business might become correctly apparent. The rule stated by the Supreme Judicial Court of Massachusetts is: "In estimating the . . . value of the business of a . . . physician, . . . the damages are to be assessed for the actual decrease in value of that business, and not merely for the decrease in such elements of the value as admit of being sold. The decrease in the money value of the petitioner's business to himself is to be estimated." *Earle vs. Commonwealth, 180 Mass. 579.* In finding the injury done to the business of a physician regard should be had for another principle of law. It has been held proper where one whose occupation or business has been interrupted or injured by an act of a stranger, and thereby damaged, to prove any circumstances in abatement of such damages which will tend to mitigate or lessen them. There are so many elements entering into the ascertainment of damage to a physician because of being compelled to move from his old site that it is particularly within the province of a jury to determine them in the light of all the facts and circumstances. The award on this claim is set aside and vacated because of the error herein pointed out.

Liability of Railroad Company for Obstructing Highway and Delaying Physician in Reaching Patient

(Terry vs. New Orleans Great Northern Railroad Co. (Miss.), 60 So. R. 729)

The Supreme Court of Mississippi reverses a judgment rendered for the defendant after the jury had been peremptorily charged to find for it on the ground, apparently, that its negligence in unlawfully obstructing the highway was not the proximate cause of the plaintiff's pain and suffering being increased and prolonged, and of the laceration to her body incident to the method pursued by the physician in delivering her of a child. That, the court holds, was error. The plaintiff, as a member of the general public, had the right to have the highway remain unobstructed so that it could be used by her for any legitimate purpose, and having a physician to travel over it to reach her bedside in order to relieve her pain and suffering was, of course, such a purpose. The defendant, under section 4049 of the Code, owed her the duty of refraining from obstructing the highway for a longer period than five minutes, and it was liable to her for any damage which resulted to her by reason of its having obstructed the highway. While it was hardly probable that its servants could have anticipated that the plaintiff would be in need of the services of a physician at the time they blocked this crossing, and that such physician in his journey to her bedside would arrive at that particular point at that particular time, they could, and ought to, have anticipated that some person traveling along the highway might be detained by reason of its being blocked, and that injury would result therefrom, either to the traveler himself or to some other person. This was sufficient to constitute the negligent blocking of the crossing the proximate cause of any injury which the plaintiff sustained by reason of her physician being detained thereby. Her physician was on his way to the bedside of the plaintiff, who was suffering intense pain and anguish incident to the abnormal presentation of a child to which she was then about to give birth. The highway necessary to be traveled by him in reaching the plaintiff's home crossed the track of the defendant's railroad. When he reached the crossing, he found it blocked by an unusually long freight train. There was, according to his testimony, no opening in this train at any point, and it continued to obstruct the highway for a period of between thirty and forty minutes. According to other testimony, the crossing was blocked for a period of about forty-five minutes. When the physician reached the plaintiff's bedside he found her so much exhausted that he was compelled to relieve her quickly of the child, which he did in about ten minutes after his arrival, some laceration of her body resulting therefrom. The court thinks it clear from the evidence that the plaintiff's suffering was prolonged by the delay of the physician in reaching her bedside, but whether she sustained any additional injury thereby was a question of fact for the jury.

RHODE ISLAND STATE MEDICAL SOCIETY

Meeting held at Providence, Sept. 4, 1913

Clinical Report on Friedmann's Vaccine

Dr. Harry L. Barnes, superintendent of the State Sanatorium for Tuberculosis at Wallum Lake, read a paper reporting 120 cases of tuberculosis treated with the Friedmann vaccine, an abstract of which follows:

In view of the fact that reports of animal experiments were meager and inconclusive, case reports of those injected with the vaccine were too scanty and the time elapsed after such injections too short to be sure of its safety or value, patients were told of this uncertainty and that the vaccine would be given them only on their own responsibility. Because of the widespread newspaper comments on this subject, with very few exceptions the patients were all exceedingly eager to take the remedy.

Dr. Friedmann injected 69 patients on April 9. On May 28, 43 were given the second injection by him and on June 8, 40 additional patients were given the first injection by Dr. Dwinell, who has charge of the Friedmann Institute in Providence. Eleven other patients were given injections shortly before admission, giving a total of 120 cases.

Sixty per cent. of the patients reported on had been observed five months after receiving the vaccine. Fifty-three per cent. had received two injections, 15 per cent. three injections, and about 6 per cent. four injections. Friedmann has stated that an infiltrate must form at the place of injection and that this will gradually disappear in the course of the next few weeks or months. As long as this tissue exists and during its gradual absorption healing will go on. From this statement it would appear that it is the induration and absorption therefrom and not the number of injections on which the improvement depends. In his paper Friedmann claimed that improvement in pulmonary cases began almost immediately after the first injection. Friedmann himself asserted that many of the patients here reported on had improved as the result of the vaccine when he saw them fifty days after the first injection. Concerning these statements, Dr. Barnes said: "We are then to-day in just as good position to judge whether these patients have made a remarkable temporary improvement as we ever shall be. Only two bed-patients were treated on Dr. Friedmann's visits because we had directed them to come last and there was not time to treat all. He selected several cases, however, after he had been informed that cavity signs were present. He examined only one case, in every instance relying on the sanatorium charts."

Smears were taken from abscesses at the site of injection, and examination of the bacilli showed them to have no acid-fast properties during the first twenty-four hours. Cultures taken from the vaccine appeared identical with those taken from the abscesses. Blood examination made from nine patients thirty-four days after injection of the vaccine were negative for tubercle bacilli. Examinations of the urine five days after the vaccine was administered were also negative for tubercle bacilli.

Two guinea-pigs and two turtles injected with the vaccine showed no signs of tuberculosis after several months.

Temperature reactions followed injections of vaccine in thirty, or 25 per cent. of all cases. As a whole these reactions were very similar to tuberculin reactions. Test examinations made during or shortly after the fever showed no focal reactions, so often found during tuberculin reactions, and as a rule the sputum was not increased during the week following the first injection.

Of 117 cases, 55 had a slight increase in the amount of sputum, 45 had a slight decrease and the remaining 17 cases had the same amounts. The average duration of the fever reaction was 2.6 days.

Usually at the end of a week a small hard nodule about the size of a pea and tender on pressure could be felt at the site of injection. Thirty per cent. of the cases failed to develop induration after the first injection. In 25 per cent. indurations resulted in abscesses and in 44 per cent. there were "satisfactory" indurations after the first few days. Indurations usually obtained their greatest size during the second week, except in those cases which developed abscesses. In the twenty-eight cases in which there were abscesses, 6 were slight, 14 moderate and 8 severe. Only four abscesses were reported among 83 men, while 24 of the 47 women developed abscesses. Most of the abscesses ruptured spontaneously between the third and sixth week after the injection.

There was no increase of leukocytes on the day following the inoculation and no marked leukocytosis during the reaction.

Dr. Barnes described minutely cases of various types. Of the 120 cases, tubercle bacilli had at some time been found in 99, or 82 per cent. Of the remaining 21 cases, there had been both hemoptysis and pleurisy in 7 cases, hemoptysis alone in 5 cases, pleurisy alone in 3 cases and the subcutaneous tuberculin tests in addition to physical signs in 4 cases. Most of these patients were second-stage patients. Only 5 were far advanced and only 1 was near death when the vaccine was given. Of 113 patients, 110 had received sanatorium treatment for periods varying from a few days to twenty-four months, during which they had gained from one to fifty-seven pounds. Had all the patients been discharged from the institution on the day the first treatment was given, their condition would have been classified as follows: arrested, 12; apparently arrested, 3; quiescent, 20; improved, 53, and unimproved, 32.

Friedmann has asserted that soon after the first administration of the vaccine there occurs a striking subjective improvement in practically all of the symptoms of the disease. The majority of the patients continued to cough much the same as such patients usually do cough in sanatoriums. Many improved in this respect and some did not. No unusual improvement was noted, but some patients coughed much worse after the administration of the vaccine.

Of 74 patients whose twenty-four-hour amount of sputum was measured the sputum was decreased in quantity in 56 per cent., showed no change in 12 per cent. and increased in 31 per cent. Of 74 control patients the amount of sputum was reduced in 51 per cent., remained the same in 11 per cent. and was increased in 37 per cent. This comparison is slightly in favor of those taking the vaccine. Fifteen per cent. of the 47 patients whose sputum had been positive before inoculation showed no tubercle bacilli four months after the first injection.

Barnes believes that, taken as a whole, the patients' appetites remained about the same except in those who had temperature reactions, in several of whom the appetite was worse.

Forty-two per cent. gained weight in amounts ranging from ¼ pound to 28½ pounds. Fifty-seven per cent. lost weight in amounts ranging from ¼ pound to 15½ pounds. Only about 18 per cent. of the patients under ordinary sanatorium treatment lose weight. In his judgment, hypnotics have been used fully as frequently in the vaccine treated as in other cases.

As Friedmann laid much stress on the relief of chest pain and discomfort, 70 patients were questioned in regard to this symptom between two and four months after the first injection. Of these, 28 had no pain before or after, 23 had the same amount, 14 less and 5 had more.

"From this," said Barnes, "we certainly cannot subscribe to Friedmann's statement that soon after the injection of his vaccine the patients lose all their troubles."

The analysis of temperature charts shows not only that the vaccine does not control but also that it induces fever. Friedmann claims that hemoptysis is never observed in consequence of or following the injection. An analysis of the records shows that the incidence of hemoptysis was slightly greater among those who took the vaccine than among those treated by ordinary methods.

In 115 cases physical signs before the first treatment were compared with the physical signs at the last recorded examination. The signs were rated as being about the same in 57 cases, as more in 35 cases and less in 23 cases. Taken as a whole, there certainly was no unusual tendency toward disappearance of signs.

On September 1, when the statistics of the present results were compiled, the average time which had elapsed since the first injection was 120 days, or about a month less than the average sanatorium residence of patients. The present condition of only 85 patients is known, and as compared with their condition at the time of the first injection of vaccine, 17 are better, 34 the same and 34 worse. From this it appears that 40 per cent. of the patients in this series are not in as good condition as when they received their first injection. The proportion of patients discharged from the sanatorium as unimproved under ordinary forms of treatment has never exceeded 23 per cent.

The unfavorable result in many cases appears to be due to the increased activity of the pulmonary lesions as a part of and following reaction to the vaccine. In several cases the signs of increased activity have subsided or are subsiding, while in others, even after five months, there is, as yet, no signs of decreased activity. Dr. Barnes then offers the following conclusions:

"This report offers no evidence as to whether or not the vaccine can prevent tuberculosis in those who are free from it, as no healthy persons were inoculated.

"It offers no evidence as to the liability of the vaccine to induce local or general tuberculosis, as this can be determined only by necropsy or special bacteriologic work.

"One patient with joint tuberculosis showed striking improvement, which makes it desirable that similar patients who have received this vaccine should be observed and reported on by those who have had orthopedic experience. The four other patients having active tuberculosis outside the lungs have not shown unusual improvement.

"The 120 patients having pulmonary tuberculosis have shown none of the immediate and wonderful results reported by Friedmann and others before the Berlin Medical Society. On the contrary, about 17 per cent. of the cases have shown an increased activity of the disease, which would not have been expected under ordinary sanatorium treatment."

Following the reading of Dr. Barnes' report the meeting was thrown open for discussion.

Dr. Dwinell, who is at the head of the Friedmann Institute in Rhode Island, criticized Dr. Barnes for reporting cases which had received only one or two injections. He stated that the report dealt too much in statistics compiled from the records of the institution and too little with subjective symptoms as obtained from the patients. He cited some of the cases reported on, which he claimed had shown wonderful improvement. He concluded by saying that the statistics were inaccurate and the report of questionable value. Dr. T. J. Smith said that he had talked with and examined these patients at the sanatorium. They had told him they felt better. He could not understand Dr. Barnes' report or why it was made at this time.

Mr. W. L. Harris said that he had not observed the pulmonary cases, but that some of the joint cases had improved, and he thought that these cases should be observed by more physicians than were doing so at present. Dr. J. T. Farrell, who had radiographed some of the joint cases, said that they showed improvement.

Dr. Jay Perkins said that patients who had come under his observation had not shown the marked improvement they should have shown in view of statements made concerning the Friedmann vaccine. He had seen one patient who developed fever after the second injection and has continued to fail since. He believed that Dr. Barnes' statistics were accurate.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

2 *Wassermann Reaction in One Hundred Infants. K. D. Blackfan and S. T. Nicholson, Baltimore, and T. W. White, St. Louis.
3 *Wassermann Reaction in Hereditary Syphilis, in Congenital Deformities and in Various Other Conditions in Infancy. L. E. Holt, New York.
4 *Luetin Reaction in Infancy. A. Brown, New York.
5 *Results with Salvarsan in Hereditary Syphilis. L. E. Holt and A. Brown, New York.
6 *Results of Treatment with Salvarsan in Late Congenital Syphilis. G. S. Strathy and G. A. Campbell, Toronto.
7 Rapid Clinical Method for Estimation of Total Fat in Infants' Stools. D. M. Cowie and W. S. Hubbard, Ann Arbor.

2. Wassermann Reaction in 100 Infants.—In this investigation the serums from 101 infants, irrespective of the reason for which they were in the hospital, were tested. The technic employed was that advocated by Wassermann, and in forty-three instances this was supplemented by tests made according to the method of Noguchi. The blood was procured by means of the suction apparatus described by Blackfan. In Group I there were 68 children, none of whom gave, on investigation of their family or past history or by physical examination, any evidence of hereditary syphilis. The Wassermann reaction was negative in 66, doubtful in 1 and positive in 1. The Noguchi modification was made in 43 of the cases in this group, and verified the results of the Wassermann test; i. e., 41 serums were negative, 1 was doubtful and 1 was positive. In Group II no clinical evidences of hereditary syphilis were found in 30 infants. In 2 infants the family history was suggestive. In 1 infant, the family and past history and the physical examination were suggestive of syphilis. The Wassermann reaction was negative in 32 of the infants and positive in 1 infant.

3. Wassermann Reaction in Hereditary Syphilis, Etc.—Holt claims that cases of hereditary syphilis almost invariably respond positively to the Wassermann test, even when previously treated by mercury, unless the treatment has been very thorough and protracted. After the use of salvarsan it has been his experience that it disappears much more regularly and earlier, but even then in most cases only after repeated injections. Of 178 tests made in hospital patients showing no definite signs of syphilis, positive reactions were obtained in but eleven and five of these were shown on fuller investigation or subsequent findings to be pretty clearly syphilitic. Two of the remaining six were doubtfully so. The great portion of congenital deformities Holt believes have no relation to syphilis, since not a single positive reaction was obtained in fifty-six consecutive cases.

Of sixty-two patients suffering from malnutrition or marasmus, only five gave a positive reaction, and are included in the group above mentioned. Of the remaining fifty-seven, nearly one-third had very considerable enlargement of the spleen or liver, or both. Since the cases examined were selected from a much larger number, as those most likely to be syphilitic, Holt cannot regard syphilis as a common cause of marasmus, certainly in the patients admitted to the Babies' Hospital. Since the error, when one exists, is almost invariably on the positive side, the technic of those who find a very large proportion of positive reactions among maramus patients in institutions is open to suspicion, he claims.

4. Luetin Reaction in Infancy.—In all Brown made 134 tests. Thirty-four were in patients with hereditary syphilis, and 100 in controls. Of the syphilitic infants all but four gave a positive luetin reaction. In the 100 controls, ninety-six were definitely negative and four gave a doubtful reaction. All of the negative cases were also negative to the Wassermann test. In all the cases regarded as syphilitic the diagnosis was confirmed by the Wassermann reaction and the clinical history. Of the syphilitic patients with a negative luetin reaction, all four were cases of severe infections and either the hemoglobin was very low or the skin much thickened so that one could not be certain of a positive reaction. Of the thirty positive luetin cases, fifteen showed small pustules; the other fifteen reacted in the form of a definite inflammatory papule. In addition it was observed that the more energetic the treatment the more distinct was the reaction. Especially was this the case after salvarsan injections. There were fourteen infants in whom the test was repeated after injections of salvarsan; of these, eight became negative during an average period of five months after the first injection of salvarsan. In each instance the Wassermann reaction corresponded with the luetin test. i. e., it became negative at or about the same time. In the remaining six positive cases the reaction was present at the time of the last test made, which averaged three and a half months after the first injection of salvarsan. In this group also the Wassermann corresponded with the luetin test.

5. Salvarsan in Hereditary Syphilis.—Holt and Brown summarize their paper as follows:

> 1. Immediate and striking benefit follows the injection of salvarsan in hereditary syphilis, and this is seen in many patients in whom mercury has been used with little or no apparent benefit. 2. Salvarsan must be given intravenously; with the technic which we have described its administration is not difficult and it is practically free from danger. 3. A single dose of salvarsan does not cure hereditary syphilis, although it often removes the visible symptoms. Relapses, however, are to be expected unless the dose is repeated. With present experience it seems advisable to repeat the injections at intervals for one year, even though no symptoms are present. 4. The best results in hereditary syphilis are undoubtedly obtained by the early use of salvarsan followed by mercurial treatment. 5. Even with the aid of the Wassermann reaction it is difficult to say when a child with hereditary syphilis is actually cured.

6. Salvarsan in Congenital Syphilis.—The authors' eighteen patients improved clinically under salvarsan treatment. The intensity of the Wassermann reaction diminished steadily with frequently repeated full doses, but in nine patients over 4 years, who received four doses or more, only two became negative, and that after eight and nine doses. They found that the younger the child, the more quickly does the Wassermann reaction become negative. They have not found the administration of salvarsan by intravenous injection in children to produce any bad effects.

10. Therapeutic Artificial Pneumothorax.—In sixteen cases in which the treatment has been tried by King and Mills two have shown marked and apparently permanent improvement, six have shown temporary or slight improvement, in one case hemorrhages have apparently been controlled, in one case of lung abscess no improvement followed, while in six cases, on account of pleural adhesions, either no gas could be injected or not enough to produce any sufficient collapse.

11. Tuberculosis of Kidney.—Fifty-eight cases of suspected renal tuberculosis were examined by Keene and Laird by the combined clinical, Bloch and subcutaneous laboratory methods. Twenty-two cases were proven, seven by operation and fifteen by subsequent clinical course, to have tuberculosis of the genito-urinary tract; twenty-nine were proven, three by operation and twenty-six by subsequent clinical course, to be non-tuberculous; seven cases were still clinically doubtful. By the Bloch method of inoculation, seventeen cases were positive, forty negative, and one doubtful, due to the same cause. In the clinically proven cases of tuberculosis, therefore, 77.3 per cent. were positive by both laboratory methods. The seven clinically doubtful cases gave negative results by both methods.

Of the clinically proven negative cases all but one gave negative results, and this was positive by both the Bloch and subcutaneous methods. This case was brought to operation on account of the positive laboratory findings; the apparently affected kidney was exposed and split, and showed, macroscopically, an interstitial nephritis and no evidence of tuberculous involvement. Two of the proven positive cases which gave negative laboratory results were closed cases, the ureter of the affected side being obstructed; one had advanced bilateral renal involvement, which shortly caused death; the other two were frank cases of unilateral renal tuberculosis. There were two clinically positive cases, each giving negative results by each of the two laboratory methods and positive by the other. Another positive case showed numerous tubercle bacilli in the inguinal glands of the pig at the expiration of ten days, and only one small focus of infection in the spleen of the other pig at the end of six weeks.

The authors conclude that the kidney is the primary site of disease in tuberculosis of the female urinary tract; as a rule the infection originates from a focus in some other organ and gains entrance to the kidney by way of the blood-stream. The pathology varies greatly in kind as well as in degree, but a definite type usually predominates, altering both the pathologic and clinical pictures. Subjective symptoms referable to the kidney disease are by no means characteristic; they are often entirely lacking, may be expressed by a dull, aching sensation in the lumbar region or by attacks of colic resembling calculus. The most prominent symptoms are those referable to deranged bladder function; starting with painless polyuria, all degrees of dysuria are met, including the most intense strangury and even incontinence. These symptoms may be decidedly intermittent in their severity, with intervals of comparative comfort. A cystitis which does not readily yield to the usual appropriate measures should arouse the suspicion of renal tuberculosis. Some degree of pyuria is the rule; hematuria the exception. Intermittent pyuria suggests tuberculosis of the kidney. Pyuria without demonstrable bacteria by smear or culture in a catheterized specimen is likewise suggestive. Albuminuria is usually present, but small in amount compared to the degree of renal involvement.

In the absence of mixed infection the temperature is normal or shows only a slight evening elevation; irregular fever, with chills and sweats is evidence of a mixed infection or a more generally disseminated tuberculous process. The palpatory findings are dependent on the type and extent of the pathologic changes. While enlargement of the diseased kidney is usually manifest, it is important to remember that compensatory hypertrophy of the kidney may be given erroneous conclusions in determining the diseased organ. Thickening of the vaginal portion of the ureter is of value in diagnosis but by no means characteristic of tuberculous infection. The tuberculin reaction is of doubtful value; the subcutaneous injection should be employed and its results are significant only in the presence of increased kidney or bladder symptoms. By far the most important agent in determining the diagnosis is the cystoscope, which in the majority of cases shows a picture so characteristic that the nature of the infection is at once recognized. Only by its use can we decide the extent of disease as well as the condition of the opposite kidney as regards both its anatomic and functional integrity.

The diagnosis of renal tuberculosis should be made in every suspected case by the combined clinical and laboratory examination. The Bloch method of inoculation of guinea-pigs should be used, because it is equal in reliability to the older method, and the diagnosis may be made in at least 77.3 per cent. of cases in ten days compared to six weeks by the subcutaneous or intraperitoneal methods, which should also be used as controls. A positive laboratory result by either method determines the diagnosis of tuberculosis of the genito-urinary tract; of renal tuberculosis in the female, the exact focus in the male to be determined by additional clinical and laboratory means. A single negative laboratory result, regardless of thoroughness of examination, does not determine an absolute negative diagnosis of renal tuberculosis, as the manifestations of this disease are essentially intermittent. Negative results obtained in three successive weekly examinations should, however, bear considerable weight in the diagnosis.

16. **Polyneuritic Form of Acute Poliomyelitis.**—Leopold cites the case of a young female who, without any previous illness, was suddenly seized with vomiting, fever, pain in the head and back, followed in several days by pain and paralysis in the lower limbs, together with paralysis of the bladder. The important physical symptoms were loss of patellar tendon reflexes and unsymmetric paralysis of both lower limbs, with partial areas of hypesthesia. There was bladder paralysis. In addition there was marked tenderness on pressure over the nerve trunks in the paralyzed extremities, which persisted until death, two months after the onset. At necropsy the heart, lungs, spleen and liver showed no changes. The kidneys showed cloudy swelling. A few punctate hemorrhages were seen in the visceral pericardium. No exudate was noted in the meninges of the brain or spinal cord. The vessels were injected. The cord in the lumbar region was somewhat softer than in the other portions, and on section showed a reddish-gray area in both anterior horns.

Microscopic sections were made from various levels of the spinal cord and medulla oblongata. These sections were stained with thionin hemalum and acid-fuchsin, by Weigert's stain, and by the Marchi stain. Only one peripheral nerve and portion of one muscle were obtained and these were from the anterior aspect of the right thigh, near Poupart's ligament. A portion of the nerve was placed immediately in osmic acid and teazed after twenty-four hours. Another portion was placed in Muller's fluid and studied by the Weigert, hemalum and acid-fuchsin stains. There was no evidence of an acute or subacute inflammatory process, and no distinct degenerative changes were noted. The hemalum-acid-fuchsin stain showed slight increase in the connective tissue. There was no round-celled infiltration. The osmic acid showed slight swelling of the fibers, some granulation of the myelin, but no breaking up into droplets. Most of the fibers were normal with Weigert's stain. The section of muscle showed no round-celled infiltration, no swelling or atrophy of fibers. The striations could be seen, but were not sharply defined. In the medulla oblongata no changes were noted. The cervical and thoracic areas of the spinal cord showed no changes. In the lumbar area stained with the hemalum-acid-fuchsin the meninges showed an intense round-celled infiltration. The pial vessels were dilated and intensely engorged with blood. Around and within the anterior and posterior roots the round-celled infiltration was intense, and the capillaries were intensely dilated. The anterior horns showed the characteristic picture of the subacute stage of an acute poliomyelitis. The left anterior horn was more involved than the right. The capillaries were injected, the round-celled infiltration was marked, and the cells showing a clear protoplasmic area around the nucleus. Many lymphoid cells, a few connective-tissue and polymorphonuclear cells were also seen. The ganglion cells had practically disappeared as only a few were seen, and those remaining were atrophied. With the Nissl stain the disappearance of the ganglion cells and the varying grades of degeneration of those remaining were most marked. No changes were seen in the posterior horns or in the white matter. The Weigert stain showed no sclerosis. These changes were noted in the second, third, fourth and fifth lumbar segments. The changes found in the lumbar region of the spinal cord were those of an acute poliomyelitis in the reparative stage. The anterior horns were practically destroyed. Intense inflammation was noted in the meninges and around the posterior roots. Most interesting was the exudate and inflammation of the spinal roots. The peripheral nerve showed no evidence of a primary neuritis.

27. **Plication of Thoracic Aorta.**—In the light of present knowledge Matas and Allen hold that the direct intervention of surgery in the treatment of aortic aneurysm must be restricted to explorations, both abdominal and thoracic, which will permit us to ascertain the relations of the aneurysmal sac to the parent vessel. In a certain number of cases of saccular aneurysm, it may be possible to obliterate the communications leading from the sac to the artery by the method of intrasaccular suture. In the majority of cases the operation will have to be limited to methods which will simply tend to reduce the circulation in the sac and thus favor the coagulation of its contents. This may be accomplished by any of the classical methods of wiring or by narrowing the lumen of the vessel immediately above or below the aneurysm, by the use of constricting agents, whether metallic (Halsted or Matas-Allen aluminum bands), or tissue strips (aponeurosis, Nassetti; aortic, Halsted), or by suture methods, such as the plicating procedure which has been the special object of the authors' investigations.

29. **Gastric and Pancreatic Carcinoma.**—The conclusions gathered by Schumann from a review of the literature are that secondary invasion of the pancreas is a somewhat infrequent sequel of pyloric or duodenal carcinoma and that in a certain group of cases, in which the pancreas is attacked early in the course of the disease, there may arise a mutual functional compensation between stomach and pancreas, which permits both organs to satisfactoritly perform their duties, with a decided absence of symptoms of disease of either, even though there may be extensive destruction of tissue.

31. Abstracted in THE JOURNAL, Jan. 4, 1913, p. 73.

36. **Purpura of Bladder.**—Kidd cites a case of secondary purpura confined to the bladder and arising in a bacterial infection of the tonsil. The patient, female, aged 12 years, was admitted to the hospital with the history that on Nov. 29, at 8 p. m., she felt a sudden desire to pass water and during the act experienced a sharp stabbing pain starting in the left iliac region and spreading into the vulva. Between 8 p. m. and 9:30 p. m. she passed water four times, each time noticing a similar pain which lasted only as long as water was passing and ceased at once at the end of the act. At 9:30 p. m. she passed water again and this time inspected it. It was full of blood. An aching pain came on in the left iliac region when she went to bed and lasted all night and the whole of the next day. Urine was passed once in the night and five times during the next day to the time of admission into the hospital at 5 o'clock in the afternoon. The patient looked ill and was pale and anemic. Temperature, pulse and respiration normal. Tongue clean and moist. Heart, lungs and alimentary system normal. There was a follicular tonsillitis on the left side and some slight enlargement of the lymph-nodes on the left side of the neck which were tender to the touch. The skin showed no petechiae. The gums were healthy. There was deep tenderness over the bladder region, especially on the left side. The urine was full of blood-clots and contained bright red blood diffused throughout. The patient was put to bed. By the next morning the bleeding had disappeared and the pain had ceased. Further examination elicited the following facts: Roentgenoscopy was negative. Cystoscopy: The bladder was filled with 8 ounces of oxycyanate of mercury solution 1 to 4,000. Both ureters appeared healthy. The bladder wall for the greater part appeared pale and healthy, but scattered irregularly over fundus and trigone were seen patches of submucous hemorrhages varying in shapes and sizes, some linear, some stellate. The greater number were scattered over the fundus. There was no ulceration and no sign of miliary tubercles. Kidd came to the conclusion that it was either a purpuric condition of the bladder wall or a primary blood-infection of tuberculosis at its very onset.

61. **Properties of Normal Sheep-Serum.**—Surface and Routt found that fresh normal sheep-serum contains a complement capable of dissolving sensitized sheep corpuscles. Sheep-serum is relatively poor in hemolytic complement. It rapidly loses its complement ability on standing. Fresh normal sheep-serum is able to prevent the action of guinea-pig complement. In the fresh serum this inhibiting property is partially masked by the native complement in the sheep-serum. If the sheep-serum is heated just sufficiently to destroy its complement the inhibiting property remains and can be clearly demonstrated. Heating the sheep-serum to temperatures below 52 C. increases its inhibiting properties. Heating at temperatures higher than this tends to destroy this property. If the serum is heated to 60 C. or beyond, both its complement and its antihemolytic property are destroyed. There is an apparent auxilytic action of the guinea-pig complement on the complement of the sheep-serum. This inhibiting property of sheep-serum is not due to complement fixation by antibodies in the hemolytic rabbit-serum. It is probably not due to any precipitate which may be formed by the mixture of guinea-pig and sheep-serum. The evidence indicates that there is a true anticomplement (against guinea-pig complement) in fresh normal sheep-serum. This is present in relatively small amounts, and most of its action is masked by the sheep complement. If the complement is removed from the sheep-serum the anti-complement becomes manifest. The anti-complement is destroyed by heating at 60 C. and higher.

63. **Tuberculosis and Malignant Growths.**—Harris cites the case of a man 45 years of age who presented clinical signs and symptoms indicative of laryngeal neoplasm. The lungs and other organs were normal as far as could be determined by clinical methods. Repeated sputum examinations showed no acid-fast bacilli present; the Wassermann reaction was negative. Operation was decided on, and when the initial incision was made, an irregular growth was seen protruding just between the junction of the thyroid cartilages. Microscopic section showed it to be a distinct epidermoid carcinoma, and a complete laryngectomy was performed with removal of the adjacent lymph-nodes, which latter, however, appeared normal. When the larynx was laid open by a longitudinal incision along the anterior junction of the thyroid cartilages it showed in the gross a definite nodule located just to the left of the median line on the inner side of the thyroid cartilage. The tumor had penetrated the structures and projected slightly on the external surface. It measured 3.5x3x5 centimeters, was of a gray color and presented an irregular surface and outline.

A sectioned surface from within outward through the nodule and the underlying cartilage showed the external gray color extending for a depth of .5 centimeter toward the interior, after which was an area of white color suggesting in certain places caseation which extended down to the cartilage. Between the two zones was an irregular line of demarcation, the white area extending by irregular projections into the overlying gray or tumor zone. The whitish zone which represents the tuberculosis infiltrated considerably beyond the limits of the tumor in the space between the mucosa and the cartilage. The accompanying glands of the excised larynx were normal in size and in appearance.

Microscopic study of serial sections from the summit of the nodule to the cartilage and also of the area immediately surrounding the tumor mass showed the following: the gray zone described in the gross was a distinct epidermoid carcinoma of the spino-cellular type. The deeper cells of the neoplasm were quite rounded and were deeply stained, while the upper part showed more flattened cells with oxyphilic protoplasm, among which were numerous epithelial pearls or "birds' nests." In the stroma of the lower portion were seen epithelioid cell infiltrations with lymphoid and plasma cells scattered here and there. These infiltrations arose from underlying well-defined miliary tubercles, which latter presented a central area of caseation with circumferentially arranged epithelioid cells, a few plasma and lymphoid cells and an occasional giant cell. There was an attempt at repair of these miliary tubercles as evidenced by the connective tissue zone surrounding them. A few scattered tubercles and a diffuse tuberculous infiltration were present beyond the tumor's margin extending between the mucosa and the cartilage. Smears from the caseous areas when stained by Gabbett's method showed a few acid-fast bacilli present. Microscopic study of the lymph-nodes revealed nothing abnormal.

It is now over one year since the time of operation and no evidences of recurrence of either condition are present. The patient has gained over thirty pounds in weight, is of a ruddy color, and apparently in the best of health. It is Harris' impression that the tuberculosis formed a primary pathologic soil on which the tumor probably thus provoked continued to flourish and the tuberculosis in part yielded.

66. **Intravascular Implantation of Rat Tumors.**—The intravascular implantation of tumor tissue was studied by Weil in connection with two types of tumors, a sarcoma and an adeno-carcinoma (Flexner-Jobling strain). A small, nonulcerated, non-necrotic tumor was aseptically removed and cut into minute pieces, so that eventually the mass appeared to have the consistency of a mush. To this mush were added ten parts by volume of .85 per cent. of salt solution. The mixture was thoroughly shaken for a few minutes, and then allowed to stand until the larger particles had settled. The supernatant fluid contained large numbers of isolated cells and a smaller number of cellular masses, composed of aggregates of from three to fifteen or more individual cells. This material passed easily through the needle that was used, and was apparently very well borne by the rats. The injections are made into the external jugular in quantities ranging from 0.5 to 1 cubic centimeter. Only two animals of the entire number treated in this manner died within a few minutes of the injection.

Twenty-one normal rats received intravenous injections of sarcoma suspension. Of these, sixteen presented on autopsy macroscopic evidence of pulmonary tumors. Of the five which failed to show pulmonary tumors three were killed within fourteen days of the injection, and of these three two showed tumors on microscopic examination. Therefore, sixteen of the eighteen rats that were examined more than two weeks after injection presented visible tumors. The size and the number of these pulmonary plants varied within wide limits in any one series, depending on the length of time that was allowed to elapse between the injection and the autopsy. In the earliest specimens the lung appears dotted over with numerous whitish points no larger than the head of a pin. In the later specimens, up to four weeks or more, the tumors have reached the size of peas, are partly confluent, and occupy a very considerable area of pulmonary tissue. These larger tumors, when cut through, present the typical central necrosis which is so characteristic of the subcutaneous plants. There are few other changes of importance. Exceptionally, there is some pulmonary congestion, but never, so far as this series permits of generalization, any pleurisy, either fibrinous or serous. In lungs occupied by fairly large tumors there is often moderate emphysema, and not infrequently there are areas of consolidation, or of hemorrhage in the immediate environment of the tumors. The other viscera show no marked changes.

84. See abstract 34, p. 622, in THE JOURNAL, Aug. 23, 1913.

86. **Potassio-Mercuric Iodid.**—MacFarlan recommends this drug as being a most effective antiseptic. For purulent ophthalmia, 1 to 10,000 is a good dilution; for ordinary antiseptic work, 1 to 2,000 will be applicable. It has a marked influence when diluted 1 to 2,000 in alcohol and used on a swab when locally applied in diphtheria and scarlet fever in reducing the infective inflammation. In erysipelas the local application stops the mischief most rapidly.

89. **Treatment of Varicose Ulcer.**—Williams cites the case of a large, stout woman, aged 50, doing ordinary farm and dairy household work, whose leg was swollen from old phlebitis and was covered with abundant varices. The leg was abraded Feb. 1, 1913, at the junction of middle and lower third anteriorly and a deep ulcer followed. On May 1 this ulcer measured 2 by 3 inches, and the whole leg and foot were swollen. The patient was unable to abandon her work and give the leg a rest. The general treatment was by means of Blaud's pill.

Local treatment: Soft, well-ripened full cream cheese to which was added a mixture of equal parts of cream and water. The whole was worked into a soft mass. The water and cream were added to prevent drying. This was kept in an ordinary jelly glass. Some of it was spread on a piece of gauze large enough just to cover the ulcer. The application was made morning, noon and night. The patient continued all her domestic duties. The application was painful for the first hour or hour and a half; then the pain subsided and the sore was comfortable until the cheese dissolved. When the empty gauze settled down on the sore it was irritating. The cheese disappeared in five or six hours. The ulcer filled rapidly. May 20 the ulcer was fully healed, no scab even remaining. Williams suggests that it is possible that the salt in the ripe cheese may be responsible for the pain of the application. Patients have not reported as much pain with the soft unsalted cheese curd, though the progress has not been as rapid as in the present case.

101. Self-Retaining Perineal Retractor.—Gelpi's retractor is composed of two sharp tenacula, so constructed that, when applied to the perineum, they remain securely in place, retracting the tissues on either side of the vaginal outlet, without the necessity of assistants to hold the tenacula where they belong. The instrument is simply a self-retaining double tenaculum. It is intended to take the place of the tenacula or Smith-hooks.

103. Serodiagnosis of Pregnancy.—The authors performed this test about sixty times on fifty patients. Three cases of known pregnancy from seventh to ninth month were positive. Three normal cases, from the first to the sixth day after delivery, gave positive reactions. Two ectopic gestations, ten days after operation, gave positive reactions. Two abortions, one three days after the birth of a six months' fetus, the other two months after abortion, with retained secundines, both gave positive reaction. (The latter case was about three months pregnant when the abortion was performed.) One stillbirth, ten days after delivery, gave a negative reaction. One patient with pernicious vomiting, who had not menstruated for two months, and where pregnancy was suspected, gave a positive reaction. One patient at the menopause, who had not menstruated for six months, and who was not pregnant, gave a negative reaction. Two large fibroids, negative. Six patients with pelvic inflammation gave a negative reaction. Ten women who were not pregnant gave negative reactions. These cases included malaria, syphilis, tuberculosis, suppurating abscess of tooth, typhoid, dermatitis herpetiformis, chronic interstitial nephritis, amebic dysentery and other intestinal parasites. Thirteen men gave negative reactions. These cases included typhoid, syphilis, amebic dysentery, uncinariasis, tuberculosis and minor complaints. Four normal men gave negative reactions.

One woman, suffering with acute nephritis and delirious, gave a positive reaction. At autopsy she was proved to be not pregnant. No control of this serum was made, and when they returned to get serum for another reaction the patient was dead. One man gave a positive reaction. The serum, however, was taken just after eating, and no control was made. The patient never returned to the clinic; therefore, his serum could not be retested. Jamison and Cole believe that the serodiagnosis of pregnancy is of definite value, and that when proper controls of the serum and placenta are made that the test is as reliable as any other serodiagnostic method.

104. Treatment of Diphtheria.—Wilson claims that the carriers are best treated by sunshine, segregation and "vaccine therapy." The best results in the treatment of the disease he says are obtained by large doses of concentrated antitoxin, 10,000 units being the initial dose, given intramuscularly, with a period of twenty-four hours between doses, the membrane being the chief guide for repeating the dose, except, of course, in the laryngeal type, and in this type the stenosis and cyanosis serve as guides.

2. **Nomenclature of Tuberculin Doses.**—Codd would select as a final unit the smallest dose likely to be given. For this unit a name *must* be found, and it should be an "unappropriated" Greek letter, with an associated word with meaning suitable to its minute dimensions. Therefore he suggests the letter ψ and the word psilon, which may be conveniently translated "shred," "residue" or "atom." Thus fractions may be obviated, the dose being given in psilons until it reaches the cubic millimeter, and then be given in cubic millimeters until it reaches the cubic centimeter. Another suggestion is the abolition of the practice of speaking of the dose of TR in terms of milligrams of the original bacillary substance, when three-fifths of that substance is no longer present. It is just like speaking of a dose of liquor strychninae, not as 5 minims, or as 1/20 grain, but as the original weight of nux vomica bean from which this quantity of liquid had been made. If, however, clinicians still wish to prescribe TR in terms of weight of the original bacillary substance, it would still be practicable to use the symbol ψ for 100,000 mg. of original bacillary substance of TR and its quantity would be the same as if the dose had been expressed in the Continental fashion—that is, in cubic centimeters of tuberculin fluid. In the method of prescribing tuberculin adopted at the General Hospital, Wolverhampton, they use the psilon unit and the cubic millimeter unit. The cubic centimeter unit is used only when the dose has attained unity or beyond. If this method were generally adopted, Codd says, it would render the use of tuberculin more popular and more intelligible to busy practitioners who do not give their whole time to unraveling these ponderously expressed fractions.

15. **Psychologic Conception of Disease.**—Brock maintains that health consists in an effective, disease in an ineffective, reaction of the organism to its environment. Organisms moving in highly complex environments have developed a unique instrument of adjustment—namely, intelligence—to help them to deal adequately with such environments. Much of what, by a confusion of thought, is called "mental disease" is simply an abnormal reaction of such an organism to its environment—a misuse by it of this intellectual instrument of adjustment. *Natura non facit saltum.* Life proceeds cautiously, repeating again and again the reactions she has found serviceable, before proceeding to experiment further. The repetition, however, is for the sake of the advance; an organism which contents itself with marking time is doomed. Brock aims to demonstrate that certain diseases are best understood from a geneticopsychologic point of view, and that, accordingly, it is first and foremost by the employment of educational methods that we can best ensure the prevention of these diseases in the future. Some of the accompaniments of disease are not themselves, strictly speaking, pathologic. Thus inflammation may be looked on as a perfectly healthy and "normal" reaction to an extraneous stimulus of relatively infrequent occurrence. Or again, in the "mental" field, certain conduct on the part of highly gifted and far-seeing persons is often branded as "cranky" or even insane, when, as a matter of fact, it may have been necessitated by, or at least may form a quite healthy and useful protest against, certain pathologic manifestations in the social environment.

18. **Congenital Defect of Abdominal Muscles.**—On reflecting the skin of the abdominal wall Thatcher was at once struck by the almost complete absence of muscular tissue in the usual situations. Only for an inch or so below the costal margin was there any trace of the recti, each being represented by a thin indefinite band of fibers. Transverse sections through the normal position of the recti above and below the umbilicus, and also through the anterior part of the lumbar region, were stained by van Gieson's method, and no muscular tissue could be recognized in them. The psoas and other posterior abdominal muscles, the thoracic and perineal muscles and the diaphragm seemed normal.' The apex of the bladder was attached to the region of the umbilicus by the remains of the urachus, which was only half an inch long, and took the form of a longitudinal band of fibrous tissue. There was also another cord-like band about an inch long which connected the anterior wall of the bladder to the anterior abdominal wall. The bladder was enormously dilated and hypertrophied. It measured 3 inches from apex to base, and 2 inches across at its widest part. When it was opened by an anterior incision, the wall was found to be between ¼ and ⅜ inch in thickness, and was very firm. The urethral and ureteral orifices were not dilated in any way, and a large probe passed easily from the bladder through the urethra, and vice versa. A fine probe could with difficulty be passed into the ureteral openings, and there was no sign of kinking. It had previously been found impossible to regurgitate urine from the bladder into the ureters by pressure over the viscus, although it could easily be expressed from the urethra. Similarly, on pressing over the ureters, the resistance was so marked that it was doubtful whether any urine passed on into the bladder or not.

Sections cut from the bladder wall in a longitudinal direction showed a great increase in the fibrous tissue elements in all three coats, especially the submucous. The muscular coat was much broken up by this fibrous tissue, the stroma penetrating it from the subperitoneal and submucous layers. The lining epithelium showed catarrh. Both ureters were greatly dilated and tortuous, closely resembling both in size and general appearance the small intestine which lay over them. The walls were thinned, and the dilatation ended abruptly at the bladder, for the intramural portion was very narrow. The ureters entered at their usual situation. They showed no sign of kinking, and were patent throughout. The right kidney was small, with marked hydronephrosis, the left about the usual size, with the pelvis but little dilated. In both the fetal lobulation was well marked. The suprarenals appeared healthy, and the relations between bladder and rectum showed no abnormality. Both testicles were found lying free just below the kidneys, and seemed normal in every way. The stomach was narrow and contracted, the bowel and pancreas normal, with no dilatation of any part of the former. The liver and spleen showed no change. There was no sign of recent or old peritonitis. In the right lung there were considerable patches of bronchopneumonia and collapse in all three lobes, this being the cause of death. The abdominal wall during life was very lax and the thorax markedly prow-shaped anteriorly. There was some asymmetry of the face and pinnae of the ears, and slight congenital dislocation of the hips. The urinary functions had been carried on quite satisfactorily, and the child had thriven well until it developed bronchopneumonia, of which it died at the age of 2 months.

21. **Development of Giant-Cells in Vitro.**—In observations on cultures of spleen tissue Weil observed that the presence of foreign particles caused a definite sequence in the migration of different forms of the wandering cells. The polymorphonuclear leukocytes were the first cells to respond and to aggregate themselves about foreign masses. These were shortly followed by lymphocytes. Following these at an interval of from twenty-four to forty-eight hours, there appeared a large mononuclear and protoplasmic cell which had the characters of an endothelial cell. By the time of the appearance of this cell, some of the polymorphonuclear cells were undergoing disintegration. These large endothelial cells had phagocytic qualities and tended to surround the foreign particles in the medium. By keeping accurate records of the numbers of cells migrating to a point it was possible to account for the number of nuclei (within a narrow limit of error) of the cells which migrated to the part. This count was compared with the numbers of nuclei determined in stained sections at the end of the observations. Weil has not observed the fusion of cells to form multinucleate ones, save when the cells involved were undergoing degeneration. When this process of fusion occurred, the cells did not exhibit subsequent phagocytic activity. He has, however, obtained multinucleate characters in cells lacking any sign of degeneration and still showing power to engulf foreign particles. These giant-cells were obtained in a process of nuclear division without visible protoplasmic change. It would thus appear from Weil's observations that *in vitro* the multinucleated cell arising from the large mononuclear endothelial cell has the same mode of origin as the multinucleate cells of fixed tissues as are constantly observed in cultures of connective- and muscle-tissue cells.

22. **New Method of Marking Paraffin Blocks.**—Harvey's procedure consists in embedding in the same paraffin block as the tissue a thin pencil of colored paraffin wax having a melting-point somewhat higher than that of the embedding mass. While this mass is molten, a length of colored wax pencil, sufficiently long to project above the block molds, is placed vertically in the liquid wax in any desired relation to the tissue; this projection of the pencil renders manipulations more easy. The block is then cooled, all protruding paraffin pencil is broken off, and the block is ready for cutting. By this means a clear and definite mark obtains throughout the depth of the block.

25. **Epidemic Disease in Rabbits.**—The epidemic disease in rabbits which the authors describe and which resembles so closely in its morbid anatomy the disease produced experimentally by the inoculation of Schmorl's bacillus is caused by a bacillus which in many of its morphologic characters is similar to *B. necrosis* (Schmorl), but which differs from it in two essential points—its motility and its aerobic character.

27. **Thyroid.**—Edmunds asserts that the thyroid in dogs hinders the assimilation of sugar: the parathyroid glands favor it.

31. **Adrenal Hypernephroma and Sex Characters.**—Abnormal sex characters do not always occur together with adrenal hypernephroma; the present position of our knowledge concerning their relationship to these tumors is summarized by Glynn and Hewetson as follows: 1. In children they are almost invariably present in the form of hirsutes and often other abnormalities (seventeen cases of hypernephroma collected; in sixteen, namely, thirteen females and three males, sex abnormalities present). 2. In adult females before the menopause they are frequently present (twelve cases collected; sex abnormalities present in seven, while in two others menstrual disturbances occurred before death). 3. In females after the menopause they are not recorded, though a growth of hair on the face or change in the voice, etc., might be thought worthy of note (*eight cases collected*). 4. In adult males they are probably invariably absent. In this connection it is of great interest that adrenal cortical rests or bilateral hyperplasia of the adrenal cortex was noted in 15 per cent. of female pseudohermaphrodites, but in only 0.7 per cent. of male pseudohermaphrodites. 5. There is no evidence that hypernephroma in the kidney, which has totally different histologic structure from that in the adrenal, is ever associated with abnormal sex characters.

32. **Reproduction of Blood-Constituents.**—After taking 10 liters of blood from an immunized horse, O'Brien noted the following: The number of white cells varies widely and irregularly. Very small differences are found in the differential count. The hemolytic titer remains practically constant, showing variations of at most 10 per cent. from the initial figure. The total amount of salts present does not decrease, but may be increased 10 per cent. The content of all other blood constituents falls, the hemoglobin and number of red cells falling together to 50 or 60 per cent. of the initial figure. The color index of the new red cells remains at the normal figure. The curve of volume of the red cells does not correspond very closely with that of the number of red cells. The curves of total proteins and of diphtheria antitoxin show a fairly close relationship.

33. **"Lecithin" in Complement-Containing Serums.**—Cruickshank and Mackie found that the introduction of lecithin into complement-containing serum of the guinea-pig does not materially alter the complement dose; in the case of rabbit's serum the complement activity is frequently increased. The albumin fraction from a serum treated with lecithin is as actively hemolytic for sensitized corpuscles as the original complement, while the globulin fraction retains the property of effectively acting with ordinary albumin fraction. The addition of lecithin to ordinary albumin fraction after separation does not enhance the complement activity of the fraction. The lecithin must be mixed rapidly with the serum, or with the water used for dilution, in order to produce the effect described; slow admixture does not yield an active lecithin-albumin fraction. The albumin fraction of a serum treated with lecithin is "absorbed" by complement-absorbing agents; it can also replace complement in the Wassermann reaction. The activity of the lecithin-albumin fraction is dependent on the presence of "complement" in the original serum. Lecithins differ markedly with regard to their power to produce the *alterations described*; a large number of preparations are quite inefficient.

The authors consider that the experiments are of interest as having a bearing on the nature of complement action. It has been demonstrated that, by the use of certain lecithins, the character of the components of complement are markedly altered, and that the complement activity in the case of certain serums may even be increased. They are of opinion that the results cannot be explained by supposing that incomplete splitting of the complement occurs, nor, on the theory of Bronfenbrenner and Noguchi, that the lecithin activates the complement in the albumin fraction in the way in which, for example, alanin does in these authors' experiments. They suggest that the lecithin acts by rendering active a component or complement which is normally present in an inactive or latent state. In the case of guinea-pig's serum this component resembles ordinary middle-piece in its properties, but differs from it in not being precipitable by the passage of carbon dioxid gas. Some modification of or addition to this theory is, however, necessary in order to explain the increase of complement activity which results with certain rabbit serums merely on the addition of lecithin.

35 *Experimental Radiotherapy of Ovaries. (Les résultats expérimentaux de l'irradiation des ovaires.) A. Lacassagne.
36 *Fatal Chorea during Pregnancy. (De la mort chez les choréiques pendant la grossesse.) G. Lepage.
37 **Diabetes and Pregnancy.* A. Fruhinsholz.

35. Experimental Roentgen-Ray Exposures of the Ovaries.—Lacassagne found that only with high dosage was it possible to sterilize rabbits with the Roentgen rays; in dogs even this was not possible, a number of follicles persisting intact. He thinks that these results testify to the folly of applying the Roentgen rays to sterilize women, as the ovaries are less accessible to the rays in women than in animals. Even if it were possible to accomplish this with intensive exposures, the danger of injury of adjacent organs, intestines, etc., renders it impossible of application. At the same time it seems evident that the Roentgen rays have a special destructive action on the tissues of fibromas and myomas. They also seem to have a destructive action on the riper follicles, and consequently prevent the menstruation otherwise connected with these destroyed follicles. But the exposures must be repeated as other follicles mature. Consequently the practical conclusion from his research is that the exposures may prove useful in causing the retrogression of uterine fibromas; they may also interfere with menstruation by small doses of the rays applied regularly to act on the riper follicles as they develop.

36. Fatal Chorea in Pregnant Women.—Lepage's patient was a nervous Jewess of 25 at the second or third month of her second pregnancy. She complained of restlessness and insomnia and he noticed that there was a slight tendency to motor incoordination in her left arm. He advised her to go to a sanatorium, saying that isolation was needed and supervision of the tendency to choreic movements; no one else had noticed them at that time. She would not go to a sanatorium; the diet was restricted to milk and vegetables and sedatives were given but the disturbances progressively increased until by the end of two weeks there were maniacal excitement and intense, incessant chorea, pulse 110, no fever. An erythema developed on the left arm and chest and the sixteenth day there was incontinence of urine and feces. The latter symptom is universally regarded as of bad omen and the pregnancy was interrupted. The choreic movements diminished in intensity thereafter but the psychic disturbances continued, and the general condition grew rapidly worse, with jaundice, the liver painful and the uterine cervix was seen to be blackish. The woman died the eighteenth day after the first symptoms of the chorea. Lepage has been studying the literature on the subject, and gives summaries of twenty cases in which the women died with no attempt being made to evacuate the uterus. Eleven of the women were in their first pregnancy; five in the second, and two in the fourth. Mental disturbances had preceded the chorea in several cases and the pregnancy was at the third to the seventh month in a number; others had reached term.

In thirteen other cases the uterus had been emptied as a therapeutic measure. Only seven of the women were in their first pregnancy. In four cases the women died within twenty-four hours after the induced abortion; in three others at the third day and in two others at the tenth and twelfth days. The necropsy findings were always negative except for endocarditic lesions in a few cases; softening of the brain was also noted in a few. Only seven of the total thirty-three cases date since 1907. In another group of five cases of severe chorea in pregnant women, induction of abortion was followed by the subsidence of the chorea and recovery. One of these women was in a very serious condition when the uterus was evacuated; pulse 120, subdelirium, scarcely any sleep and an eruption resembling measles four days after the abortion.

A fatal outcome may be feared when the choreic movements are extremely severe, preventing eating and sleep and not yielding to sedatives; when mental disturbances precede or accompany the chorea; when the pulse and temperature run up, and there is a morbilliform eruption. Interruption of the pregnancy when this stage is reached is of little use but cannot be refused as a last resort.

37. Diabetes and Pregnancy.—Fruhinsholz has noticed that the children of diabetic women are liable to be large but they die either during delivery or in three or four days thereafter. There are other analogies with syphilis; both entail an "inaptitude for life" although the new-born child may be large and appear to be healthy. Women should be examined for both syphilis and diabetes when the fetus dies near term or at or soon following delivery. On the other hand, diabetes does not entail abortion so regularly as syphilis, and while therapeutic measures may have a decided influence in restoring conditions practically to normal in case of syphilis, with diabetes the circumstances are not so favorable. It seems impossible to act favorably on the fetus of a diabetic woman by any treatment given her. He insists consequently that diabetic women should be warned against conception. A pregnancy is almost certain to aggravate the diabetes, while there is little hope of a healthy offspring. The child is almost inevitably doomed to die at or almost immediately following its birth.

July, VII, No. 7, pp. 361-420

38 Occult Hemorrhage in the Stomach or Intestines. (Critique expérimentale de differents procédés en usage pour la recherche des hémorragies occultes du tube digestif.) G. L. Hallez. Concluded in No. 8.
39 *Hereditary Nature of Gastric Ulcer. F. Dauwe.
40 Perforation of Gastric Cancer: Twelve Cases. Jalsson.

39. Heredity of Gastric Cancer.—Dauwe reports eight cases in which the father or mother of the patient had also had ulceration in the stomach at some time. The tendency to recurrence, to excessive gastric secretion, and the development of the ulcer at an early age are special features of these hereditary cases. A hereditary tendency was evident in about 25 per cent. of all his gastric ulcer cases. Accepting a peptic origin for the cancer, and accepting a primary hypersecretion as responsible for the peptic corrosion, the gastric ulcer is thus traced to an indirect nervous origin, which readily explains any hereditary tendency.

Archives de Médecine des Enfants, Paris

45 *Epilepsy in Children. J. Comby.

41. Spastic Paraplegia in Older Children Due to Inherited Syphilis.—Marfan describes a form of spastic paraplegia for which inherited syphilis is responsible. In the first case of the kind he encountered (1894) it developed slowly and progressively in a boy of 8, and a syphilitic origin was suspected but no benefit was derived from specific treatment. In several of the six cases he reports the Wassermann reaction was positive. Left untreated, this heredosyphilitic paraplegia continues an inexorably progressive course, and when the lesions have been long installed the destruction wrought is irreparable. In his first case no benefit was derived from either mercury or iodid. After the discovery of salvarsan, he began to treat this patient with it, and this has apparently arrested the progress of the disease as it has been stationary since.

If treatment is commenced in the early stages of the paraplegia, there is every prospect of its arresting the progress and possibly realizing a complete cure.

On account of the hopefulness of early treatment and the slight chance of influencing the paraplegia after serious lesions are once installed, the early recognition of the condition is of extreme importance. It should be suspected whenever a child limps or shows any other disturbance in his gait. The paraplegia commenced in all his cases between the ages of 5 and 12. At first merely a very slight limp, the trouble beginning insidiously and slowly progressing until after a year or year and a half the child was unable to walk to school. The gait is of the spastic type; the child drags his feet, not lifting the toes, and he balances from left to right and right to left at each step. At first the disturbance may be more pronounced on one side. The legs are held stiff and lifted up all in one piece, the child finding it difficult or impossible to bend the hip, thigh and ankle. This difficulty in flexing the joints is the main disturbance in the gait. There is also a tendency to pes equinus and varus or valgus and the knees knock together. This spastic rigidity is scarcely appreciable when the child is seated or reclining. The legs are slightly rotated inward, with adduction, but they can be moved easily and the joints flexed except that as the foot is passively flexed upward the Achilles tendon may oppose a fibrous resistance.

The muscles are not weak nor hard nor atrophied, and the spastic rigidity of the legs is accompanied by only very slight paresis. But even in repose the tendon reflexes are seen to be much exaggerated and there is epileptoid trembling of the foot. Rubbing the front of the leg or tickling the sole induces the Babinski sign. The electric responses are normal or nearly so, and there are no sensory disturbances, no pains, no atrophy or weakness of the muscle. By the end of ten years in his first case the patient was then 18, and was unable to walk unless supported by another person, but the affection had not changed its character in any way; there were still no sensory or sphincter disturbances and no atrophy of muscles. Another differential point is that there are generally the pupil signs characteristic of syphilis. In three of his six cases there was interstitial keratitis and two of the children were mentally backward. Marfan discusses the pathologic changes in the spinal cord probably responsible for the paraplegia, but has had no opportunity to examine a case post mortem.

42. **Cool Baths in Excessive Heat.**—Schreiber and Dorlencourt tabulate some statistics which confirm anew the way in which babies die on days of excessive heat or the day after. They then report extensive research on puppies exposed to high temperature as in the summer heated term. The results confirm the directly injurious exclusive action of the high temperature, and that it is proportional to the height of the temperature. Both the naturally fed and the artificially fed suffered alike. Humidity in the air seemed to reduce the resisting powers. The puppies kept at 30 to 37 C. (86 to 98.6 F.) developed fever, with dyspnea and they lost flesh and were very restless. At 50 C. (122 F.) there was actual heat stroke, speedily fatal, but no digestive disturbances were noted. All the puppies died kept at a temperature of 40 C. (104 F.). In one series of experiments, artificially fed puppies had in addition to the other symptoms digestive disturbances, with diarrhea in two and vomiting in one. On the other hand, they found that cool baths had a marked influence on the overheated puppies, the temperature and the respiration returning to normal almost immediately. Even with pronounced heat stroke, the cool bath corrected conditions so that the puppy did not show any ill results from his experiences. The experiments all teach, they declare, the importance of immediate cool baths for infants suffering from the excessive heat, applying the baths extensively and energetically.

45. **Epilepsy in Children.**—Comby thinks that epilepsy is often acquired from some preventable cause. It is not a hereditary neurosis and hence should not be regarded as an inheritable taint. The ostracism of a family with an epileptic member, he declares, is based on misapprehension. Epilepsy is generally regarded as hereditary and incurable when in fact it is neither. In its various degrees it is common in children but it is rare in adults and extremely rare in the elderly. This can mean only that the children outgrow the tendency in time. Some comparatively insignificant obstetrical trauma is responsible for epilepsy later in many cases, he is convinced. The traumatic lesion may be so minute that it escapes the closest examination, but yet it is enough to bring on epileptic seizures while it does not manifest its existence in any way during the intervals. The effect of this obstetrical trauma, however, cannot be regarded as in any sense an inherited affection.

All the evidence to date is in favor of the assumption that there is always some lesion at the bottom of the epilepsy; it is not a neurosis but an organic affection of the nervous system. The lesion may have been acquired during intrauterine existence, but aside from the obstetric cases it is usually acquired after birth, and there is almost invariably a history of some more or less severe infectious disease affecting the brain. In some cases an accidental intoxication makes an impression on the brain enough to stamp it with the taint of epilepsy. He relates a case of this latter kind: A child of 3 slept in a room with a defective flue letting coal gas escape. After a winter of this he developed epileptiform attacks. They subsided during the summer, but after another winter of the coal gas he became a confirmed epileptic and the seizures have recurred regularly during the nine years since. The carbon monoxid evidently induced an acute and localized encephalitis which in its turn generated the epilepsy. In other cases Comby has known hemiplegia to follow coal-gas poisoning. Epilepsy consequently, he insists, is the result either of traumatic (obstetrical, etc.) origin, or it is due to encephalitis accompanying an acute infectious disease, or it is the result of the action of some poison.

47. **Removal of the Bladder on Account of Multiple Tumors.**—Heresco comments on the gravity of the clinical outlook with the bladder filled up with a new growth, and also on the gravity of total cystectomy. But his experience with four cases in which he removed the entire bladder and sutured both ureters to the skin at the point of the incision has proved that this operative treatment may prove unexpectedly satisfactory. By bringing the mouths of the ureters close together in the hypogastric region one urinal suffices for both, and is easily managed by the patient. It permits also direct disinfection of the kidney pelvis on both sides. A long catheter is run into each ureter thus conveying the urine into the urinal which may be strapped to the leg. One of his four patients was a woman and she neglected to keep up the sterilizing injections into the kidney pelvis as instructed, and she succumbed ten months later to pyelonephritis. The trouble was a cancer in one of the other cases and this patient also succumbed after a few months to the progress of his malignant disease. But the two other patients are still in good health, one after more than two years, the other nearly as

long. The prostate is normal in both, the ureters permeable and the general health excellent. They were men of 50 and 45. The first had a diffuse infiltrated cauliflower-like cancroid nearly filling the bladder; the tumor in the second case so filled the bladder that even the finger could not be introduced. In this latter case the patient refused to allow the entire bladder to be removed until after two palliative operations. The final cystectomy was difficult and took an hour and a half and the postoperative weakness was extreme; only 100 gm. of turbid urine were voided in the following twenty-four hours. This amount slowly increased but the patient was tormented with singultus and vomiting two or three days and there was slight fever, but then the man began to improve rapidly as the kidney pelvis was rinsed out with a disinfectant three or four times a day for two weeks. This is almost the only technic for cystectomy which readily permits this repeated systematic disinfection of the kidney pelvis on both sides, and yet it is to this that the ultimate favorable outcome is due in large measure. Heresco found it an advantage to drain through the perineum after the cystectomy, and he also emphasizes the necessity for working the ureters loose as far up as possible before fastening them to the skin. Seven illustrations accompany the article.

48. **The Nitrogen Output in the Urine in Kidney and Heart Disease.**—Boulud states that study of additional cases with the necropsy findings has confirmed in every respect his statements in regard to the clinical and diagnostic importance of the index of the proportion of nitrogen in the urine. They were summarized in The Journal, 1912, lix, 1751. He now has a record of forty cases and he gives the details of each, with the post-mortem findings, and draws some general laws based thereon which throw light on the pathologic conditions of which the "azoturic coefficient" is one of the manifestations.

50. **Why the Prostate Causes Symptoms.**—Deton emphasizes that besides the loss of elasticity in the prostate and its enlargement, elderly people have to contend in addition with a reduction in the expelling force of the bladder. This latter factor should not be overlooked in study of "prostatism."

51. **Antimeningococcus Serum in Treatment of Acute Gonorrheal Epididymitis.**—Schmutz reviews the various measures in vogue for treating the complications of gonorrhea, particularly epididymitis, and relates extensive experience in his own and others' practice with antimeningococcus serum, particularly in France and Roumania. The serum is generally injected into the muscles of the thigh and three injections are usually sufficient. The spontaneous pain is the first symptom to subside under this serotherapy, the patients sleep well after the first night and the epididymis becomes less sensitive. The temperature drops the day after the injection as a rule, and the superficial inflammation loses its angry aspect. The deep tissues do not show much benefit until after two or three days, when the swelling of the parts begins to go down. The effusion in the vaginalis noticed in nine of fifty cases was all absorbed, and in some instances in forty-eight hours. By the tenth day the epididymis was soft throughout, except possibly for a tiny bunch still hard but not tender, and there is every reason to suppose that this will be absorbed in the course of time. In five of the six patients reexamined later, the epididymis was apparently normal in every respect but the sixth still had the tiny hard lump, probably retrogressing at the time. Schmutz therefore concludes his review by commending as superior this method of treatment; the only contra-indications, he says, are possible anaphylaxis, from preceding serotherapy, and mixed infection, which may annul the effect of the serotherapy.

65 *Retroperitoneal Cysts Originating in Wolffian Body. (Kyste wolffien du mésocolon descendant.) C. Jacquot and C. Fairise.

64. **Diagnosis of Extra-Uterine Pregnancy.**—Chaput reports a case in which there was no sign of intraperitoneal hemorrhage, no hematocele anywhere and no disturbance in menstruation, but the diagnosis of extra-uterine pregnancy was rendered certain by attacks of intense pain, in the region of one ovary, the recurring paroxysms of pain being separated by intervals of entire freedom from pain. The paroxysms recurred unmodified by any and all measures to relieve the pain. In a second case there was a hematocele lying like a cap over the top of the uterus and not accessible to palpation through the vagina.

65. **Retroperitoneal Cysts Originating in Wolffian Body.**—Jacquot and Fairise report the details of a case in a girl of 18 with the minute necropsy findings and review thirteen other cases from the literature. The age of the patients ranged from a few months to 65 years. The embryonal origin entails a tendency to a malignant evolution while the complications of the tumor may prove directly fatal. Seven pages of bibliography are given and the necessity for prompt operative removal of such cysts is reiterated in conclusion.

68 *Retention of Salt in Kidney Disease with Dropsy with Subnormal Salt Content of Blood. (Rétention chlorurée hypochlorémique dans les néphrites hydropigènes.) C. Achard and A. Ribot.

68. **Retention of Sodium Chlorid with Subnormal Content in the Blood.**—Achard and Ribot give a number of examples to show the variable effect of the ingestion of salt on the proportion eliminated in various diseases. In one of their cases a man with chronic interstitial nephritis, the kidneys impermeable to urea, with retention of nitrogen and extensive

edema, yet had only from 4.3 to 4.5 gm. of sodium chlorid per thousand in the blood-serum. In a second case a tuberculous young man with acute nephritis and dropsy had only 5.1 gm. per thousand of the chlorid in his blood-serum and two weeks later this dropped to 4.56 gm. In the peritoneal effusion, however, the proportion even with this latter figure was 5.1 gm., while the percentage of urea was practically the same in both serum and ascitic fluid. These facts and others related suggest that in the retention of salt in kidney disease hitherto unsuspected extrarenal factors are involved. These factors must evidently be sought in the tissues themselves and in the organic fluids.

85 *Fascia Flaps and Implants. (Die freie Fascientransplantation.) P. Kornew.

81. **Ivory Supports after Resection of Bone.**—König says that tissue grows into an ivory implant in time, fastening it firmly and thus curing pseudarthrosis and similar aseptic lesions ideally. In an infected focus it does not heal in place so well and is liable to maintain the characteristics of a foreign body. He reports extensive experimental and clinical experience with eighty cases, profusely illustrated. Cutting a screw-thread and numerous small depressions in the ivory helps in its solidity after healing. In one of the cases an ivory artificial humerus was implanted; it locked in the shoulder joint and the lower end cut to a point set rigidly in the short stump of the patient's own humerus below. Sometimes he uses wire to hold the ivory implant in place. Eighteen illustrations accompany the article, including two of a woman of 68 whose left lower jaw had been replaced with an ivory prothesis which looks and works like a normal jaw and causes no disturbance.

84. **Splenomegaly with Anemia.**—Grützner's patient was a girl of 10 who had had rachitis and was under treatment for helminthiasis when the spleen began to enlarge and signs of a hemorrhagic diathesis followed, with progressive anemia threatening to prove speedily fatal unless something could be done to arrest it. The syndrome suggested Banti's disease but had not lasted long enough for cirrhosis of the liver and ascites to develop. The blood picture began to improve at once after the splenectomy and by the fifth day the reds had doubled in numbers and soon reached the normal figure. The blood picture has persisted normal during the year since. The spleen measured 19x12x4.5 and weighed 450 gm.

85. **Fascia Grafts.**—Kornew's article is based on both experimental and clinical experiences and fills ninety-four pages. Grafts of fascia heal finely in place, he states, irrespective of their size. A fascia graft is peculiarly useful to close gaps in the bone and muscle wall of the thorax and defects in the pleura. Also to reenforce hernia operations, a sheet of fascia having superior advantages for this purpose over all other methods. A fascia flap is often likewise the best means to close a defect in the abdominal walls, and is the method of choice for closing the internal femoral ring. A strip of fascia is also the best means to draw up the anus in treatment of prolapse of the rectum. Also for fixation of the testicle in case it rides up. Mobilization of the ankylosed mandibular joint is also possible with the aid of a fascia implant; in fact, this is by far the simplest and most effectual method for the purpose.

89 Comparison of Technics for Serodiagnosis. (Die Hermann-Perutz'che Reaktion im Vergleich zur Wassermann'schen Reaktion.) F. Bräutigam.

86. **Intestinal Auto-Intoxication.**—Albu reviews the present conceptions in regard to auto-intoxication from the intestines, and states that the new biochemical facts recently learned in regard to the internal secretions, hormones, etc., make it necessary to revise the conception of this subject on this new basis. Only when these newly acquired biochemical data are duly taken into consideration will the theories conform to the facts.

87. **Beriberi.**—Caspari and Moszkowski have been studying this subject for years and here relate the findings in metabolic research on Dr. Moszkowski extending over a period of 230 days, during which the main article in his diet was polished rice. In the course of time symptoms developed suggesting the cardiac form of beriberi. Positive experiments on pigeons and animals were conducted at the same time. In the pigeons, as also in the case of Dr. Moszkowski, all the symptoms subsided in an amazingly short time when small amounts of an extract of rice bran were given in addition to the previous diet. The metabolic findings showed in the course of the experiment great destruction of albumin, to be explained only as the result of severe intoxication.

There can be no doubt, they say, judging from these experiences, that beriberi is not the result of a deficiency in the diet but of some toxic plus, and thus it is essentially an intoxication. They think that the last link in the chain of evidence is provided by one of their numerous experiences: Pigeons were fed for months on hens' eggs with a little salt and sugar. The birds thrived and were in excellent health. Then some polished rice was added to the egg, and the pigeons every one developed polyneuritis after a longer or shorter interval while the controls remained healthy. The toxic substance causing the beriberi is not necessarily present in the food, they say; it may originate in the body under the influence of the polished-rice diet. This assumption is confirmed by the beneficial influence of purgatives which Abderhalden and Lampé have reported as almost constant in their research on polyneuritis in swine.

93 *The Horsehair-Worm as Parasite of Man. (Gordius als Parasit des Menschen.) H. Herzog.

90. Compressive Treatment of the Lungs.—Spengler has had extensive experience with both artificially induced pneumothorax and operations to mobilize the chest wall and thus induce the compression of the lung. He tries to induce the pneumothorax first; only when this fails does he attempt the thoracoplastic operation. He gives the history of both operations and describes his technic and the indications for each. He has been able to trace to date all but five of the ninety-three patients he has treated with the therapeutic pneumothorax. Twenty-three, that is, 26 per cent., are clinically cured of their pulmonary tuberculosis; 41 per cent. have not quite completed the course, but the improvement to date is very encouraging. In only 21 per cent. was the desired result not realized, and in most of these cases the conditions prevented a complete pneumothorax. Thus favorable results were realized in sixty-nine of the eighty-eight, namely, in over 78 per cent. In eighteen other cases the chest wall was resected; the patients were thereby cured of their pulmonary disease in four cases and materially improved in twelve others; two died, one from the effect of the operation itself, the other from aspiration complications. Sauerbruch has a record of fifty-six cases of this kind without perforation of the cavity and twelve of the patients were cured, seventeen materially improved and fifteen improved, while the condition seemed to grow worse afterward in four cases and two patients died from the effects of the operation and six have died since from the progress of their disease. In ten cases in which the cavity had perforated, four were materially improved or cured and one is still under treatment; the others have died. This group includes three recoveries although the empyema had perforated into a bronchus or into the artificial pneumothorax. The cases with tendency to shriveling of the lung tissue are particularly adapted for the thoracoplastic technic, especially when the shriveling process is so pronounced that the trachea has been drawn to one side and there is some dyspnea. In two of Sauerbruch's cases of this type the dyspnea subsided after the plastic operation. The lower lobe must be compressed first.

93. Horsehair-Worm as Human Parasite.—Herzog reports a case in which the description of the worm passed in the stools seemed to agree with the description of the gordius, and a second case in which the worm was absolutely identified as the gordius. It was expelled in the stool of a boy of nearly 3, in company with several specimens of the oxyuris. He says that it is the nineteenth authentic case on record. The child had been nervous for a few weeks, complaining of abdominal pain and waking up screaming at night, but the appetite and stools were apparently normal except that five weeks before the gordius was expelled there had been blood in the stools. Whether the gordius or the oxyuris was responsible for this is a question. The child since the expulsion of the worm has been in constantly good health.

94. Pernicious Malaria.—Marchiafava comments on the wonderful improvement realized in recent years in the campaign against malaria in Italy, especially in the extensive marshes around Rome. Scarcely a week passed in the old days without the necropsy of one or more cases of pernicious malaria at the San Spirito hospital, but last year, up to August 15, there had not been a fatal case. Cases of pernicious malaria still develop, however, in the malarial districts and he emphasizes the fact that persons acquiring malaria for the first time seem to be peculiarly prone to develop the pernicious type. This fact is sustained not only by the history of the cases—the sufferers are generally persons just arriving in the district—but also by the fact that the spleen in his cases of pernicious malaria was not much enlarged and the congestion and enlargement were evidently of quite recent date. The appearance resembles that of the spleen in typhoid fever, differing only in the melanosis and the extreme softness. In all his experience he never found the spleen chronically enlarged in a case of pernicious malaria. By the time the individual has developed the chronic enlargement of the spleen he has had time to become practically immunized against the pernicious type of the malarial infection.

In the pernicious form quinin fails as a rule because the parasites are in such numbers and probably extremely virulent; even if they are all destroyed by the quinin the organism is flooded with toxins to an extent incompatible with survival. The only dependence can be on prophylaxis, and he reiterates the importance of this. Every workman or other person going to a malarial district for the first time should be compelled to apply for the quinin preventive treatment the very first day of his arrival and should be instructed in the methods of prophylaxis without a day's delay. The pernicious type seems to be the work of the estivo-autumnal form of the malaria parasite and the thick-film method is particularly fine for showing them up. Marchiafava adds that examination of the blood should be a routine procedure in all malarial regions whenever there is persisting fever assuming typhoid characteristics; also in all cases of jaundice with more or less fever; in children with symptoms suggesting meningitis, and in diarrhea suggesting cholera, accompanied by fever. In this way it will be possible to detect the cases of pernicious malaria possibly in time for treatment to prove effectual. Examination of the blood is not necessary in cases of unmistakable malaria.

95. Roentgenotherapy of Pulmonary Tuberculosis.—Küpferle and Bacmeister have been conducting experimental research on rabbits with financial aid from the Koch Foundation, and report that only large doses of the hard Roentgen rays seem to be able to exert a favorable influence on the tuberculous process. The action of the Roentgen rays may be effectually reenforced by other forms of radiant energy, and other measures which resemble them in their action. In none of their experimental work was it possible to destroy entirely the tuberculous process, not even in the incipient cases. The tubercle bacilli themselves did not seem to be directly injured by the Roentgen exposures; animals inoculated with them afterward developed tuberculosis. But the fibrous transformation of the tuberculous tissue under the influence of the rays checks the growth of the tubercle bacilli in the focus and protects against their spread.

97. Aseptic Mammals.—Küster extracted the young of goats by Cesarean section about a week before term and brought them up under absolutely aseptic conditions. The kids developed as normally as the controls. He thinks that the possibility of thus bringing up large mammals under absolutely aseptic conditions opens a new field for scientific research. The kid was kept in an iron and glass box stall. The floor of the stall is funnel-shaped with a paraffin oil siphon to permit the removal of excreta without interfering with the sterility of the box. An aseptic anteroom with double doors contains an electric sterilizing apparatus for the food, etc. A pair of long rubber gloves is fastened germ-tight in the opposite walls of the box stall so that a person in the anteroom can run his arms into the gloves up to the shoulder and use his hands thus inside the stall. Two persons can thus work inside the stall at the same time. The air pumped into the stall is filtered three times through cotton, the last time after it has been passed through concentrated sulphuric acid, after which the air is passed through an electric heater which heats it to 150 C.

The kid is thus kept in germ-free air and fed germ-free food; the great difficulty is to get the sterile kid into the box in a germ-free manner. The Cesarean section and extraction of the kid were done under a gauze tent kept constantly sprayed inside with hydrogen dioxid, the tent opening into the aseptic anteroom so that the kid was passed directly from the uterus to the gloved hands of the assistant in the anteroom. During the procedure the air pump was pushed to the utmost, the current of air thus sweeping through being so powerful that any germs floating in the air must have been carried out. The first kid soon died as both it and the control proved to be non-viable. The carcass dried up and was found bacteriologically sterile when examined after it had been left in the aseptic box for ten days. The second kid was kept in the aseptic box for forty-four days and continued to thrive after its release.

103. Dietetic Treatment of Cholelithiasis.—Salomon remarks that there are few fields of dietetics in which such diversity of opinions has prevailed as in the management of gall-stone trouble. He adds that we cannot hope to dissolve the stones in the gall-bladder or drive them out into the intestines by any therapeutic means at our command. The best we can do is to keep the bile system healthy. The bile ducts are too small and the pressure of the bile too weak to hope to drive the stones into the intestine by any means to stimulate the production of bile. The presence of gall-stones tends to render the stomach abnormally irritable. This irritability is manifested by the same signs and symptoms which accompany hyperacidity in the stomach. He regards this as even more important than the fact that hyperacidity is frequently encountered with cholelithiasis. The tendency to excessive secretion is felt both in the stomach and in the gall-bladder, and the hypersecretion thus may start up pain from the gall-stones just as a hitherto pain-free felon begins to throb and pain when a wave of blood pours into it.

In any event, he declares, the dietetic management of cholelithiasis during the latent stage should be the same as for hyperacidity. Cold drinks should be carefully avoided; warm drinks may be useful and a little above the usual ration of fluid should be taken, up to 2 liters. Fat is well tolerated, as also in hyperacidity. Purgatives are often directly harmful, especially their chronic use, as also with gastric hyperacidity. The main point, however, in the treatment of both hyperacidity and cholelithiasis is to cure the tendency to constipation. Normal peristalsis of the bowel is unquestionably the best means for promoting the flow of bile. Constipation should be combated by coarse food and fruit; even at the risk of fatiguing the stomach, this dietetic regulation of bowel functioning should be sought as the main desideratum. Gradual and systematic training of the gastro-intestinal canal to proper functioning is the best means to influence the cholelithiasis. Obstinate attacks of pain and fever often disappear promptly and permanently when the constipation has been conquered. This suggests that stagnation of the bile is responsible for the attacks.

104. Treatment of Eclampsia.—Wegner comments on the way in which the principles of Stroganoff's prophylactic treatment are now being adopted in many places. The most important is the shutting out of all external irritation, all noises, bright light, chilliness, unnecessary contact and pain; isolation in a dark room is enforced, the convulsions aborted and kept under control with morphin, chloral and chloroform, delivery hastened but not forced and the respiration and functioning of the heart, kidneys and skin carefully supervised. Stroganoff reports only 7 per cent. mortality in 500 cases of eclampsia treated on these principles. This includes all the cases of sepsis, hemorrhage and pneumonia; the mortality of the children was 21 per cent. That this low mortality is not due to any special mildness of the eclampsia in Russia is shown by other statistics cited from the same city with a mortality of 18 and 20 per cent.

Wegner insists that close medical surveillance is necessary for women with eclampsia and they consequently should be sent to the hospital, the sooner, the better, giving a sedative for the transportation. If the woman has to be treated at home, he advises the Stroganoff method, supplemented by venesection, withdrawing at least 500 c.c. of blood. If delivery can be brought about without force, this should be done under a general anesthetic. He reiterates in conclusion that no fluid should ever be put in the mouth of an unconscious person, and adds that eclampsia without convulsions is usually the severest form.

109. Treatment of Intermittent Claudication.—Pick reports unusually fine results from his treatment of the disturbances of peripheral arteriosclerosis. It is based on the principle of reducing the viscosity of the blood, that is, the internal friction, and promoting the circulation in general by having the patient breathe under negative atmospheric pressure, thus magnifying the pumping effect of the expansion of the lungs. He meets these indications by having the patient inhale an iodin spray, supplementing the action of the iodin on the blood by means to impede to a certain extent the intake of air into the lungs. He brings the iodin spray into an air-tight mask with valve arrangement which does not permit quite free breathing but allows unimpeded expiration. The result is physiologically identical with that of breathing under negative atmospheric pressure. The patient has to make greater efforts to breathe to get enough oxygen in addition to the spray he is inhaling. When this combination of iodin and under-pressure breathing is applied repeatedly every day for several weeks, the patients find that they can walk without the intermittent attacks of inability to use the limb in question; the pulse becomes perceptible in the region once more and the limb feels warm. This warmth is felt over the whole body, showing that the effect on the circulation is general.

Patients with peripheral angiosclerotic dysbasia do not suffer from the intermittent disturbances so often or so severely when they are climbing a hill as when they are walking on level ground. Walking up hill is more exertion and they breathe deeper, thus promoting the circulation throughout. Pick trains his patients to walk and move generally more slowly; this postpones the vascular disturbance from the muscular exertion. Otherwise the lack of adequate oxidation and the accumulation of metabolic waste bring on such acute fatigue that inability to functionate follows. A few moments' rest, however, and the fatigue waste products are swept along and the conditions return to approximately normal. One patient came to him saying that he suffered from intermittent claudication in a severe form and had not been able to feel the pulse in his left foot for six years. He had consulted nearly every prominent physician in the country without relief. After four months of treatment with the iodin spray and the impeded breathing exercises to induce negative pressure in the chest, his leg felt warm, the pulse in the foot had returned and he scarcely ever had any further disturbance in his gait. He is still zealously keeping up the treatment, amazed at the benefit in the four months to date.

113. **Frequent Cause of Intestinal Disturbances.**—For the last two years Liebermeister has had the first stool examined of each patient admitted to the internal department of the Düren public hospital in his charge, and states that among the last 100 patients, twenty-one had ascarides' ova in their stools. In some previous series the proportion was still higher. In a number of the cases the disturbances on account of which the persons had been admitted to the hospital were directly dependent on the helminthiasis and as soon as this had been cured, they were restored to health. One obese woman required an emergency operation for incarcerated hernia and ileus; the hernia was corrected but the general condition was so bad that the ileus was left unmolested; necropsy revealed that a twisted mass of innumerable ascarides in the ileum was the cause of the obstruction. A lad of 13 had ileus and a large tumor could be palpated but under internal measures both subsided but returned two days later. The stools contained numerous ova of ascarides and two courses of treatment for helminthiasis led to expulsion of twenty-five ascarides and restoration to complete health. A third example of the evil for which helminths may be responsible was a woman of 30 who had been treated for a long time for "gall-stone colics" and was finally sent to the hospital for an operation. The discovery of ascarides' ova in the stools led to postponing of the operation until after a course of treatment for the helminthiasis, but this cured at one stroke the whole trouble.

He adds that in seven of the twenty-one patients with helminths in his last hundred, the helminths were responsible for all the morbid manifestations as the latter disappeared entirely under the dose of fourteen drops oil of chenopodium with one drop oil of peppermint, divided into three capsules. One capsule is taken each hour and a powerful purge four hours after the last capsule. Four days later he has the stool examined again and if ova are still found he repeats the course. More than two courses are rarely necessary, but in one case he repeated this treatment eight times, alternating santonin with the oil of chenopodium and more than fifty ascarides were expelled. Even then ova were still encountered in the stools. Liebermeister entitles his communication "A Frequent Cause of Various Kinds of Disturbances."

123 *Seasickness and Vagotony. Friedländer.

115. **Pathology of the Adrenals.**—Helly reports a case in which, as in Kolisko's recently published case, a tumor found in an adrenal was the only probable explanation for the sudden death after a minor operation, merely pulling a tooth in Kolisko's case. In Helly's case the woman of 43 had a tendency to hypertrophy of the heart, high blood-pressure and glycosuria, and he is inclined to regard the tumor found in the adrenal as the direct primary cause for them all. The excessive functioning of the adrenal entailed by the tumor growth—which consisted of chromaffine elements—flooded the organism with epinephrin and this rendered the heart, etc., so unstable that it was unable to resist even the slight shock of a minor operation. Conditions are similar to those in the thymicolymphatic habitus in which sudden death is liable to occur from slight causes. It does not seem possible at present to detect this over-production of epinephrin and the consequent reduction of the resisting powers under its influence, but the discovery of these tumors in the adrenals throws light on certain puzzling cases of sudden death.

116. **Endemic Goiter not Due to the Drinking Water.**—This communication from the hygiene institute at Zurich embraces the results of examination of conditions in regard to the drinking water in fourteen different localities with over 5,600 examinations of individuals residing there. In some of the places the entire population was personally examined. In one town with a population of 693, 61.6 per cent. were found to have goiter; in one with 60, 77 per cent. were affected; one with 195 had 67.7 per cent. The proportion ranged in six towns from 40 to 77 per cent.; in three from 24 to 35 per cent.; in four from 1 to 12.1 per cent. No special geologic formation could be found in these endemic foci, and the drinking water cannot be incriminated as the cause for the goiter, as the distribution of goiter did not correspond to any special type of geologic formation. The endemic foci where goiter had been supposed to have been exterminated by utilizing water from another source, bringing it from a distance, have not shown any diminution of the incidence of goiter as the years pass. The investigators encountered numerous families in which nearly every member had goiter and other neighboring families in which all were free from it. They add that Bircher's statements as to the source of the water supply in certain localities were based on mistaken premises. Renewed investigation showed a different geologic formation than he had supposed.

Goiter is not known to occur spontaneously in rats at Zurich, but the investigators were able to induce it at will by taking the rats to the endemic foci, whether the animals were given the natural water to drink or the water was boiled for them, or they were not given any water or only water brought for them from Zurich. The research carried on with the rats at eight different endemic foci gave positive results in from 40 to 70 per cent. of all the experiments. The nature and origin of the water given the rats to drink had no influence on the outcome. Rats kept at Zurich and given water brought from endemic foci at first did not develop goiter but later there were a few instances of its occurrence; contact infection could not be excluded in these cases. In the endemic foci the animals developed the goiter even when they were given only water from non-goitrous regions.

119. **Addison's Disease and Pregnancy.**—Vogt comments on the far greater prevalence of Addison's disease in men than in women, and states that there is no case known of a woman with primary Addison's disease becoming pregnant and only two instances of pregnancy in secondary Addison's disease. One was reported by Barlow: a woman of 42 who had gummatous tumors in the adrenals and secondary Addison's disease bore a dead child. The other case was reported by Jacquet; pregnancy seemed normal and terminated in the birth of a viable child. After the childbirth the symptoms of Addison's disease improved to a notable extent. Vogt adds a third case to the list and in this case also the pregnancy ran a normal course and a viable child was born somewhat prematurely but the mother died suddenly the eleventh day after a brief period of vomiting and collapse. The adrenals were the seat of tuberculous processes and there was a process in one lung. In 43 per cent. of all cases of Addison's disease, according to the records, the adrenal process is accompanied by tuberculous processes elsewhere; isolated tuberculous processes in the adrenals are known in only 17 per cent. In Vogt's case there was hypoplasia of various organs and the thymicolymphatic status. The aorta was particularly narrow, the heart small, the thyroid enlarged, the thymus persisting. Vogt adds that even when there is no sign of Addison's disease simple overexertion may completely exhaust the epinephrin secretion and lead to sudden death. Comenati and Karl have reported cases of this kind in boys who died in tetanus and the adrenals were found entirely empty of epinephrin, the excessive muscular action in the tetanus having evidently exhausted the supply. At the necropsy of a young man who had died suddenly after a strenuous bicycle race, the total

absence of epinephrin from the adrenals was the only pathologic finding Schmorl could discover. He and others ascribed this fatality to the acute exhaustion of the chromaffine system by the excessive demands on the heart and muscles during the race. If the delivery in Vogt's case had been difficult, the woman would probably have died then, but as it was exceptionally easy, the end did not come until the second week. The prospects for the child are not bad; in this case the child has developed normally.

120. **Danger of Combining Morphin with General Anesthesia.**—Straub recalls a case in which a surgeon started to amputate the finger of a child under morphin alone but found it necessary to give chloroform, and the child died from arrest of the respiration. Experimental research has confirmed the assumption suggested by this case that the injurious action of morphin on the respiration center may be intensified to a dangerous extent by an anesthetic, like chloroform, which acts likewise on the respiration center. Ether has the opposite effect on the respiration center, stimulating it to increased functioning. He gives tracings of the respiration in animals s it was retarded under morphin and still more under ethyl carbamate. Other tracings show that the retarded respiration under morphin can be brought back approximately to normal by atropin. The research reported suggests that when morphin is given chloroform had better be avoided and ether used for the general anesthetic, and, further, that it is best to refrain from any combination with morphin for children as they are more susceptible to morphin than adults. The research further indicates that artificial respiration is illogical and useless when the respiration center is paralyzed.

121. **Death after Auro-Potassium Cyanid.**—This drug has been stated to be free from toxic action but Hauck reports the death of a man of 37 after a systematic course of treatment with it strictly according to directions. The treatment was for extensive lupus which had resisted all other measures, including tuberculin. The cyanid seemed to have a directly destructive action on the blood and severe hemolytic jaundice developed, fatal in less than two months after the treatment had been started.

123. **Seasickness.**—Friedländer thinks that there is a mechanical factor involved in seasickness, namely, the swaying and dragging of the stomach on the esophagus with the pitching of the ship. As an adjuvant to other measures, he warns not to load the stomach, and advises winding a bandage around the stomach to lift it up and thus remove the strain on the esophagus and reduce the swaying of the stomach. His experience with this simple mechanical measure has been very favorable. He urges its use in connection with Fischer's atropin treatment, remarking that Fischer's theoretical explanation of the nervous causes of seasickness seems logical and convincing. (It was summarized in these columns Sept. 6, 1913, p. 814.)

128 Patient Should be Informed if He Has Tuberculosis. J. Kollarits.

125. **The Pupil Sign of Vagotony.**—Somogyi writes from Koranyi's clinic to report the findings in 120 patients, including forty-two between 13 and 25, tested for the pupil phenomenon indicating excessive tonicity of the vagus nerve: The pupil dilates during deep inspiration while it contracts during expiration. This pupil sign is accompanied by irregularity of the pulse; it becomes more frequent during inspiration and slows up during expiration. The respiratory arhythmia may occur without the pupil sign but the latter was never observed isolated. Both phenomena are more frequent in younger individuals. A theoretical explanation is offered and the practical importance of this vagotonic pupil sign is emphasized. The phenomenon is the exact reverse of the pupil-dilating action of epinephrin when the tonus of the sympathetic nerve is excessively high. Vagotony is connected with the status thymicolymphaticus and also with many conditions which belong to the group of neuroses. The difficulty of recognizing this status thymicolymphaticus—which predisposes to sudden death on slight causes—renders extremely important any sign which may aid in its discovery. The most striking evidence of the vagotonic origin of this pupil phenomenon is its association with the respiratory arhythmia.

126. **Ether for Rinsing out the Inflamed Peritoneum.**—Derganc has been applying this method which Morestin and others have been advocating in France. Derganc applied it in two severe cases of peritonitis following perforation of a gastric ulcer, or an ulcer in the bowel, from a trauma. The patients were men of 28 and 36, and the operation was done the fifty-fourth or eighty-seventh hour after the perforation. In the gastric ulcer case, after sponging out the fluid found in the abdominal cavity with dry sponges, he poured in 150 gm. of ether. It made a sizzling noise as it found its way into the depths. The ether was then wiped out again at once with dry sponges. All the loops of intestine had taken on a bright red tint. In the second case the intestine was perforated at two points and he washed out the fecal masses, fluids, etc., with an abundance of hot saline, drying the parts with dry sponges afterward. Then he poured in 400 gm. of ether, wiping the parts dry again with dry sponges. Both operations were done under spinal anesthesia, draining through the pouch of Douglas, and the prompt and smooth recovery from the threatening perforation-peritonitis he ascribes to the use of the ether. (Morestin's communication on the subject was summarized in The Journal June 21, 1913, p. 1971.)

127. **Multiple Arthritis in Late Syphilis.**—Huzar reports three cases of acute multiple arthritis which seemed at first to be ordinary acute articular rheumatism. The knee is generally the joint first involved; with or without some predisposing trauma, the knee swells and becomes painful and then other joints become affected, in turn the elbow and wrist, the finger joints and the sternoclavicular articulation. The temperature may keep within normal range or may run up even to 104 F.; it is generally intermittent. The condition may persist thus for weeks and months; the general condition usually improves or grows worse parallel with the fever, but there is no suppuration in the joints involved. If the syphilitic origin of the affection is recognized in time and specific treatment instituted, conditions soon right themselves and complete restitution follows. If not, the acute phase passes into a chronic stage and various destructive processes develop which it may be impossible to influence with any measures at our command. Huzar remarks that the more we learn about the family history of old syphilitics, the more frequent becomes the discovery of latent syphilis in the mothers, and the oftener we hear of a history of past attacks of "articular rheumatism." It is beyond question that some of these "rheumatism" cases were in fact unrecognized syphilitic joint troubles. In some cases potassium iodid was given for the supposed rheumatism and thus unwittingly proper treatment had been applied. The whole course of the syphilitic polyarthritis is milder than that of acute febrile articular rheumatism, and the endocardium and serous membranes are not affected as with the latter. Nocturnal exacerbations are also characteristic. In any event, the arguments here presented impose the necessity for applying the Wassermann test and starting specific treatment in every case of multiple joint trouble which does not yield promptly to ordinary treatment. The old notion that late syphilitic processes are not accompanied by fever is no longer tenable. He advises treatment with mercury and potassium iodid, with salvarsan in case these fail. The more important German works on the subject are listed.

134 *Right-Handedness in Infants. E. Voelckel.
135 Epidemic Poliomyelitis in the Netherlands in 1912. J. C. Schlippers and C. de Lange.

131. **Roentgen Diagnosis of Pulmonary Tuberculosis in Children.**—Rach found two cases showing a three-cornered shadow with its base toward the heart and the apex extending toward the periphery. On autopsy they were found to correspond to caseated foci lying near the hilus. Ghon's primary focus can frequently be demonstrated radiographically when it can be shown by no other method. (Ghon declares that in practically all cases involvement of the lymph-nodes is secondary.) When there are negative physical findings but a positive von Pirquet and a sharply circumscribed shadow lying to the side of the hilus, the diagnosis is positive. The prognosis of this picture is the more favorable, the older the child. After 8 years of age it generally denotes a stationary tuberculosis and offers the most favorable explanation of a positive cutaneous test. Swelling and caseation of the paratracheal glands on the right are frequent, and are shown by a shadow extending outward from the median line running parallel to the trachea for a space and then rejoining the median line. It generally denotes a progressive tuberculosis involving the bronchial lymph-nodes. An interlobar pleuritis was shown in two cases by a sharp linear shadow corresponding to the interlobar fissure.

133. **Roentgenoscopy of the Infant's Stomach.**—As seen by the Roentgen ray the stomach of an infant in a standing position has the shape of an inverted retort; when lying down, that of an irregular sack. The respiratory movements of the diaphragm cause movements similar to peristalsis. The mechanism of emptying the stomach is similar to that in the adult, but there is not such marked peristalsis. Between meals the stomach is generally not contracted, but is distended with air.

134. **Right-Handedness in Infants.**—Voelckel says that the functional difference in the brain hemispheres which causes right-handedness appears first at the age of seven months and increases from that time on. Before that age there is no difference in the use of the two hands.

141 *Torsion of Spermatic Cord. (La necrosi del testicolo per torsione del cordone.) C. Viscontini.

141. **Torsion of Spermatic Cord.**—Viscontini's patient was an 8-months infant and the spermatic cord had twisted thrice around. The child was apparently healthy and thriving when it began suddenly to scream and twist, keeping this up constantly for hours; then it vomited and the mother noticed that the scrotum was swollen and hard. An operation was done on the assumption of an incarcerated hernia but the trouble proved to be torsion of the spermatic cord and the testicle was found in a state of total gangrene. The torsion evidently occurred as the testicle was descending, and this is the fourth case of the kind on record according to accessible literature. The presumptive diagnosis of incarcerated hernia in such cases leads to waste of time in trying to reduce the supposed hernia and, still worse, the maneuvers for correction and reduction injure still further the already suffering cord and testicle.

142. **Exclusion of the Pylorus with Gastro-Enterostomy.**—Mariani has applied in a case of gastroptosis and dilatation of the stomach, requiring gastro-enterostomy, a method of exclusion and fixation of the pylorus which, he says, has many points to recommend it. The stretched pylorus was kinked on itself and was sutured to the duodenum and below to the rectus muscle and subcutaneous tissue, thus not only closing it up completely and permanently but supplying a firm support for the sagging stomach. The functional results were ideal at once, but the patient succumbed during the second week to ether pneumonia. The conditions found at the site of the operation confirmed the advantages of this technic when the stomach and pylorus are stretched enough to permit it.

151 Agglutinins. (Obzor sovremennago sostoyania voprosa o phytohaemagglutinin'ax.) I. L. Yakulenko.

148. **Pyelolithotomy versus Nephrolithotomy.** — Shenker reports seventeen cases of operative treatment of kidney calculi and calls attention to the better results when the kidney pelvis is opened instead of the kidney proper. The patients recover in half the time or less with pyelolithotomy instead of nephrotomy, and the operation is much less of a strain on the system.

149. **Fat Implant to Fill Cavity in Bone.**—Perimov's patient was a girl of 16 with osteomyelitis of the tibia of four years' standing. It had been operated on fifteen months before but a fistula had persisted after the curetting. Perimov enlarged the fistula, scraped out the surface of the large cavity found in the bone and after drying it with sponges, buried in the cavity a strip of adipose tissue 7 cm. long by 4 cm. wide, taken for the purpose from the subcutaneous tissue of the abdomen. On account of the pathologic condition of the skin at the site of the bone focus there was some difficulty in suturing the wound, and the lips parted under the dressings so that the fat implant could be seen when the dressings were changed the seventh day. It had not changed in aspect at all. The outer surface was then scraped away and the defect in the skin closed by two skin flaps from each side. There was no bleeding from the fat graft as it was curetted.

Perimov does not venture to decide the question whether the graft is acting as a foreign body, merely plugging up the cavity, or whether it is being vitalized in the depths. Be this as it may, he remarks, the important fact is that the girl was completely cured of her old bone affection by the end of two months.

155 *Prophylaxis of Venereal Disease. W. Machado.

152-155. Sanitary Control of Prostitution.—A. Porto here makes an able plea for the introduction into Brazil of the method of registering prostitutes and keeping them under sanitary control as the wisest method at the disposal of the world at present for the prophylaxis of venereal disease. He discusses the subject under the four heads of individual, moral and public prophylaxis and treatment. By individual prophylaxis he means the intensive and extensive dissemination of all the medical knowledge in regard to syphilis, its contagion, transmission and its disastrous effects. He says that all the leagues and preventive organizations that have been founded have accomplished little or nothing to date. The mother organization, founded at Brussels by Dubois-Havenith, recently went out of existence, and attempts in Brazil to found a similar organization came to nothing on account of the general indifference. By public prophylaxis he means well managed sanitary control of prostitutes, and he takes up in turn the ten most widely urged objections against this system and answers them. As society is now constituted, he says, prostitution has little chance of total eradication at present, and the only thing to do is to reduce its evils as much as possible. The discovery of salvarsan is a new and powerful argument for sanitary control, as under the influence of prompt salvarsan treatment the external lesions heal over with surprising rapidity, which materially lessens the danger of infecting others.

The old objection that the patrons would be lulled into a false security by the certificate of health given the prostitute at the medical inspection, when she may have become infected immediately afterward, he answers by two statements, (1) that the primary sore is generally painful so that contact is usually avoided during this stage and under sanitary control the disease would be discovered before this stage had passed into the non-sensitive and more acutely contagious phases; (2) the certificate might specifically state "Without guarantee," just as certain French patented articles bear the stamp "Brevété, S. G. D. G." (patented, without government guarantee). The objection that sanitary control is infringing on the personal liberty of the women he answers by saying that women practicing prostitution are breaking the laws and undermining the bulwarks of the state by sapping at the foundations of the Family, and hence they have no right to complain of any infringing on their personal liberty.

To the objection that those who deal with prostitutes know the perils to which they are exposing themselves, he answers that no one but a physician can appreciate those perils at their true value. Those who have nothing to do with prostitutes and who say "Let each man assume the responsibility for his adventures," even these are not sure that syphilis may not be brought into their families by some servant or relative. In short, he concludes, it is the duty of the state to keep prostitutes and pseudo-clandestine prostitutes and periprostitutes under sanitary control, but the measures should be applied very liberally and wisely, and the abuses of the system that have been noted in other countries must be kept out at every cost. He says it will be easier to introduce a model system where nothing of the kind has ever been known than it has proved in European countries where it was a question of remodeling old systems.

Machado states that until quite recently he was opposed to sanitary control, and in fact the Academia Nacional de Medicina in 1902 voted against the introduction of any such system. But he has been converted to the necessity for it, and cites statistics from various countries showing the urgent need for it and the comparatively good results from it in France where it is systematically applied. Sanitary control was abolished in Denmark in 1906, and he quotes statistics to show that the number of cases of venereal disease in Copenhagen has increased materially since then, according to the records of physicians: from 6,666 in 1905; 7,065 in 1906, to 10,249 in 1908, while the number of cases of syphilis in 1905 was 1,277 and in 1908, 2,484. To allow prostitutes to ply their trade without sanitary control wisely applied, he declares is a crime of high treason against the prophylaxis of disease (*crime de lesa-prophylaxia*).

157. Epidemic of Diarrhea.—Andersson devotes eighty-four pages to the report of an epidemic affecting 472 of 1,235 soldiers during some maneuvers in 1910. The symptoms ranged from those of ordinary enteritis to a syndrome resembling typhoid; in some cases gastric symptoms predominated. The first case dated from Sept. 4 and the others strung along to Sept. 26. The symptoms differed from those of paratyphoid as also from proteus and colon bacillus infection and botulism. He gives a detailed study of the whole epidemic with eighteen tables under various headings. His final conclusion is that the epidemic was due to meat poisoning, although the long period during which the cases developed and the fact that a few of the sick had not eaten any meat are hard to reconcile with this conception.

158. Differentiation of Phlegmonous Angina and Diphtheria.—Charlier reviews his experience with 110 cases of the former and emphasizes the danger of mistaking true diphtheria for ordinary tonsillitis or quinsy and incising. In five cases in which this was done the patients died and in a sixth case, although the patient recovered, yet he was long in grave danger. A history of preceding attacks of peritonsillitis is a great aid in differentiation; also the age, as diphtheria affects mostly children while 83 per cent. of the peritonsillitis patients were between 16 and 39; 9 per cent. over 40, and the other 9 per cent. were between 9 and 15. Another aid in differentiation is absence of known contact with diphtheria. Tenderness of the swollen part of the throat occurs early with peritonsillitis, but Charlier has never known of this with diphtheria. There was no hoarseness in ninety-four of the 110 cases, and there was not the peculiar odor of the breath common in diphtheria. On account of the great tendency to recurrence of peritonsillitis it seems wise to operate on the tonsils in such cases. Sörensen says in regard to the danger of incision in a case of diphtheria which has been mistaken for phlegmonous angina that it is not the incision which renders the prognosis so grave in such cases but the fact that when diphtheria commences with a phlegmonous lesion it is of an exceptionally severe type. In any event, Charlier advises to be wary of using the knife for a supposed phlegmonous angina until certain of its non-diphtheric character.

SECTION ON OPHTHALMOLOGY

PAPERS† AND DISCUSSIONS

THREE OPHTHALMIC QUESTIONS

OPTOMETRY, CONSERVATION, EDUCATION *

HIRAM WOODS, M.D.
BALTIMORE

Fellow Members of the Section on Ophthalmology:

My first and very delightful duty is to welcome you to this annual gathering—an event to which we have learned to look forward not only with pleasure but also with expectations of profit. Renewal of old friendships, contact with men whom we knew first for what they were doing and then claimed as personal friends, opportunities to blurt out our ignorance to hearers who are sympathetic because they have their own to swap for ours, shaking off for the time being the responsibilities and tire of office work and yet staying in the environment in which we are most at home—these are some of the things our annual meeting affords; and they are not lightly to be turned aside.

Some years ago I heard Dr. Osler say something like this—I am not sure even that he ever put it into print, but it ought to go there and ought to be remembered: "The doctor who lives to himself is a most dogmatic and dangerous animal. The patient watches his every expression; the nurse takes what he says as law and gospel; the family waits at the foot of the steps to get the latest news, and rejoices or trembles at the great man's verdict. After a while he gets to believe it all himself. Only when he touches elbows with his fellow doctors does he reach his true level, and because of this he owes it to himself and his patients not to forsake the 'assembling of yourselves together.' "

For my own part, I could afford to do without a great many things better than I could spare the help I get from an annual pilgrimage to this Section, and I know that I have plenty of companions feeling the same way. Of the social side of this meeting I can say only that I do not know anything about it. The Minnesota men served notice some months ago that they wanted hands off; but that provision is ample, and that the man who does not have a good time will have only himself to thank, are facts apparent already to those who know our hosts, and will be apparent to those who do not in a surprisingly short time.

I beg to thank you for considering me worthy of becoming your chairman, and for electing me to that position. I shall crave your indulgence for such errors as I may make, and for such success as attends our meeting I shall ask you to give the greater part of the credit to my friend who occupies the secretary's chair. Dr. Derby has been diligent in and out of season. In all the plans and work he has been ready with thoughtful suggestions and has always been willing to assume his own and others' duties.

He, Dr. Posey, chairman of the Executive Committee, and I decided to make an effort to secure some new working material for our meetings.

One cannot but be struck at society meetings with the number of men who are evidently doing good work, thinking about the problems presented in every-day practice, and yet taking no active part in contributing to the information fund. As the late Dr. Kipp of Newark once said to me, you get at what a man really thinks better on the hotel porch or at dinner than you do in a meeting. We have tried to get some of these men on our program this year, using those who have been the Section's mainstay in the opening of discussions. I think that we have achieved considerable success, and that the program shows not only new names, but also work well worthy careful attention.

In addition to those by members of the Section, we have three papers from invited guests. The trachoma question presents economic problems which have received careful study by the United States Public Health Service. We are indebted to the kindness and interest of Surgeon-General Rupert Blue for the detail of two of his officers, Drs. McMullen and Schereschewsky, to present this subject. With the addition of Dr. Stucky we have probably the three men who know most about the geographic, social and economic sides of this dreaded disease. The Massachusetts Commission for the Blind has sent Mr. Henry Copley Green, its field agent for the conservation of sight, to present to us the big problem of saving eyes; no one has had greater experience, no one can speak more authoritatively. Mr. Herbert E. Ives of Philadelphia has kindly come to discuss the subject of light. Finally, it has been our endeavor to emphasize the pathologic side of ophthalmology. A number of men working in pathology have brought instructive specimens, and will have time to demonstrate them. We have aimed to make the program short, but there is enough to require close attention to the end of the session.

---

* Chairman's address.

† As the footnotes indicate, certain papers are here printed in abbreviated form.

OPTOMETRY

I ask your attention to a review of three matters of importance to the science of ophthalmology. The first is optometry. For years ophthalmologists have been forced to go before legislative committees and combat specious arguments in favor of elevating to a profession a large body of tradesmen. Our motive for opposing legislation desired everywhere, and now existing in thirty states, is conviction that it is the duty of a conscientious physician to oppose anything calculated to give the public false teaching on physical and medical truths. My purpose is not to repeat the arguments against such legislation, but to gather some lessons from this experience.

Optometrists have collected a not inconsiderable literature. All of us have read their articles. Refraction roblems are discussed; quotations abound from standard medical works, and, on the surface at least, there is an appearance of scientific reasoning. All the way through, one can see a gradual approach to the "vital" element in refraction. I say "vital" not in the sense of essential—though it is really that—but vital in the sense of a living organism, with its circulation, nerve-supply, functions as an end brain organ; its power, on the one hand, to produce remote symptoms, and on the other to manifest evidence of distant lesion. Usually, as the optometrist writer approaches this point, reasoning wobbles. Soon we are in the familiar torrent of abuse of "drops," laudation of "fogging," attempts to draw conclusions from ocular phenomena clearly symptomatic, and so on. Evidence is conclusive that the writer is working with a mental bias.

For whom are these men writing? Are there in the optometric fold young, ambitious and conscientious men who are deceived into thinking that they are getting the real thing when they read optometric journals? Has the establishments of the optometry course at Columbia University attracted into optometry men with perfectly honest intentions, who believe they are entering a real science because a leading university is willing to take the apparent position of endorsing it? The question is not without importance.

There is, too, an entirely different class of literature, an example being a pamphlet called "Conservation of Vision and Modern Optometry" edited by the Publicity Committee of the American Optical Company. This pamphlet was widely circulated among physicians in Maryland before and during the session of the legislature of 1912. It contains, of course, the usual hysterical claims of glaucoma from "drops," without intimation of the existence of mydriatics which can be safeguarded. A striking feature of the pamphlet is a garbled quotation from the book of the late Dr. Roosa, published in 1889, about producing glaucoma. Omissions from the paragraph, as it appears in the book itself, add greatly to its value from the optometric point of view. Another strinking thing is an attempt to make the late Drs. Norris and Oliver advise against the use of mydriatics. A statement which appears in the book of these writers in the chapter on "Examination of the Eye" is used by the Optical Company under the caption "Danger of Instilling Drops." In the book there is not a word about "danger." The student is warned against relying on a dilated pupil for routine ophthalmoscopic examination. He is at the same time told to dilate the pupil unhesitatingly under certain conditions. All this is omitted in the Optical Company's pamphlet. One unfamiliar with the original source could form no other conclusion than that Drs. Norris and Oliver were opposed to the use of mydriatics.

Finally, just a mention of two items appearing in this May issue of the *Optical Journal and Review*. They are indicative of the mental state and intentions of optometrists. The leading article is entitled "Oculist Opposes Drops in Refraction." It is written by one Herbert Dickson, M.D., of Chicago. Dr. Dickson is evidently a newcomer into the Illinois metropolis, for his name does not appear in the American Medical Directory for 1910, but does in that of two years later. The article itself is a vapid effusion with a few well-known physiologic facts and practically nothing more, except a denial of permanent weakening of accommodation from "drops." This the editor criticizes in a foot-note, and naturally, for it is the optometric Gibraltar. An editorial calls attention to the "argument" against the use of "drops" by the "Chicago oculist," who, incidentally "expects to read a paper in July at the state optical convention in Chicago, explaining his method of treating cataract without operation, and showing how his treatment can be used in cases of glaucoma and optic atrophy." The doctor adds, "I am giving out this new matter at a meeting of optometrists rather than at a medical meeting because my practice has come to me through the help of optometrists and in spite of physicians, to whom therefore I feel no gratitude."

The other item has reference to the recent amendment of the New York optometry law prohibiting the title "Doctor" unless it has been conferred by a duly authorized college prior to the passing of the amendment. An editorial in the *Optical Journal* has this: "It is believed that a number of the optical colleges will be recognized so that graduates who receive degrees from them will be entitled to use the title." It is stated that the New York State Educational Department "gave assurances" to this effect. If I am right in my inferences, the optometrists' "scientific" articles have just enough scientific veneer to fool an uninformed person, student or legislator. Their writers abuse ophthalmologists, but emphasize and welcome every sort of seeming medical endorsement—even to the extent of manufacturing it by garbled quotations. They speak with editorial favor of scheming to circumvent an amendment to a state law forbidding them to use a title which has but one popular meaning, and which they have not earned.

These are the people we are called on to oppose in their endeavor to secure professional recognition. In this work we have done more than prevent legislation in a great many states. The necessary publicity of the matter has had an educational value. It is more generally appreciated now than formerly that glasses are therapeutic means for combating the results of congenital deformity, senile changes or functional results of disease, and that the diagnosis is part of medicine. This knowledge has spread to members of legislative bodies and it is rarely necessary to argue it.

If I correctly interpret the present situation, it is of social rather than strictly scientific nature. True, the latter is its underlying feature, but it is the former which affords the optometrist his greatest strength. I do not know that I can put it better than it was put to me by a member of the Maryland legislature, who has twice helped defeat optometric legislation. Substantially what he said was this:

The optometrist has only a small part of a big science; he is not trained to know even where his sphere of activity ends; his work is full of danger to the public, for without medical training he cannot be depended on to know the difference between health and disease; yet the fact remains that he often does give satisfactory spectacles, and there is a large class of persons whom he has served for years and will probably continue to serve until he makes some blunder. He asserts that he is trying to elevate his own standards.

Then I was asked, "Cannot the medical profession propose something positive?"

I bring this question to the Section on Ophthalmology, with another: Was it wise a year ago to abolish our committee on optometry? True, the *Bulletin* of September, 1911, brought the matter up to date and contains the basic information on which we must work; but legislatures continue to meet, and the situation is constantly changing. The plans of the Council on Health and Public Instruction of the American Medical Association, for broad study of all hygienic matters, put this and all health questions in a new light. I would not be understood as yielding to the present demands of the blatant commercial optometrists, totally unqualified for professional standing, even when judged out of their own mouths. Yet I feel that the Section on Ophthalmology has not done its last duty in this optometry business, and that we still have educational and probably legislative obligations to fulfil. I believe that the first step is the selection of a capable committee of five or more of our own members to take up the matter with the Council for public protection.

CONSERVATION OF VISION

With approval of the Executive Committee, an entire session is devoted to conservation of vision, the subject to be presented by Henry Copley Greene of Boston. Choice between the terms "conservation of vision" and "prevention of blindness" is not without significance. The former includes the latter, but it goes farther, and brings within our purview influences which affect eyes functionally, and which receive but scanty treatment in our own literature. It suggests means for bridging over the critical period of school life—means developed by the thought and skill of the illuminating engineer, the architect and other professional men. It brings us in contact with the social worker, the philanthropist and altruistic organizations.

About three years ago the Russell Sage Foundation held a series of meetings in New York, to which were invited representative men and women from different spheres of work. Much valuable information was gained. Prior to the national work of the Russell Sage Foundation, a committee of the American Medical Association had been collecting data on blindness, studying not alone immediate causes, but also underlying conditions. If one will glance over reports in our Proceedings he will find much of value on every medical phase of preventable blindness. There are, also, in engineering literature and in papers written by our own members, discussions of proper methods of lighting rooms, arranging school desks, home regimen, etc. Much suggestive writing also exists: What should be done for children with defective vision but still sight enough to enable them to obtain some education? What are the functions of the district nurse and the social visitor? How shall innocent children be protected from ignorant parents? These are but examples of activities opened by the concept of conservation. The ultimate goal is to unite into one all these forces, medical, social, educational, philanthropic, moving toward physical, mental and, indeed, moral conservation.

It was with this dream, if I am not mistaken, that men and women attended the Russell Sage conferences, and it was with this ambition that they entered into the formation of a National Association. And yet, with all this information at hand, with a great foundation ready to stand behind a strong movement for conservation, with thoughtful, studious men and women anxious to throw themselves into the work, we have, so far as practical organization is concerned, hardly commenced. Some things have been done in a few states; in some they have been done better than in others, and in most not at all.

In my judgment, national movements have accomplished so much less than was hoped for because work was started before proper foundations were laid. Of what use is literature unless there are arrangements to receive and distribute it? Of what use, beyond exciting a spasmodic and temporary interest, are exhibits, unless professional and public minds have been prepared for them, and unless there exist forces to push home their lessons? What is needed is the organization, in the medical ranks of every state, of a society to keep at work till the general profession has learned its duties, the philanthropist his, the legislator his. We need leadership. It should be furnished by this Section, acting with the Council on Health and Public Instruction of the American Medical Association. Dr. Posey has carefully studied this sphere of conservation. He, and Drs. Wood and Lewis, have been asked to present a report, which they will do at our executive session.

EDUCATION

In the educational number of the *Bulletin* of the American Medical Association, issued Sept. 15, 1909, there is published under Section 8 the report of the subcommittee on diseases of the eye, ear, nose and throat. The ophthalmologists on this committee were Drs. deSchweinitz, Jackson, Standish and Wilder. Among the recommendations made was that ophthalmology, in the sense of pathologic conditions, should not be taught during the first or second year; "whether the third or fourth year of the course should be selected for the presentation of these subjects necessarily is best decided according to the arrangements of individual schools." Before beginning ophthalmology, however, the student should have certain preliminary training "in the anatomy, structural as well as regional, of the eye." He should also receive careful training in its physiology "and an arrangement should be made with the department of physiology in each medical school . . . by which the students in the year preceding that in which they receive their training in these several branches should have the opportunity of obtaining the necessary physiologic instruction." There should also be clinical demonstrations to smaller sections of the class, the student being required to make his own examinations and diagnoses. There are recommendations regarding the number of hours of instruction, didactic and clinical, subjects to be included in the course, qualifications of the instructors, etc. The last section of the report contains this: "Thus far the report has made no reference to the instruction in pathology and pathologic anatomy. . . . In the number of hours allotted, a sufficient time must be given to this particular subject to enable the student to obtain a satisfactory understanding of his clinical work, and each teacher will naturally include instruction in pathology in his course."

The recommendation that training in anatomy and physiology should immediately precede the study of abnormal conditions is important because the medical student of to-day has so many things to think about that he is in a more or less chronic state of mental acrobatism. If the superstructure is not put on before the foundation has had time to crumble, he can have only insecure knowledge; the farther his pathologic is removed from his anatomic and physiologic training, the less apt is he to understand the former or remember either. The same is true of the relation of a specialty to general pathologic principles: and here is a question for every conscientious teacher to ask himself—how well qualified is he to teach his own specialty on the basis of general pathology? Probably he received no such systematic training when he was a student twenty years or so ago; diseases were taught by symptoms, and treatment was based largely on the physiologic action of drugs. Do teachers sufficiently appreciate the change they must make in conception, and realize how readily the eye lends itself to illustration of general pathologic principles? It is no uncommon thing to find that our best students forget, after two or three years, the diagnostic signs of common eye diseases. The reason is not hard to find. They had not been given a proper thinking basis because the specialty had not been harnessed to pathology.

To determine the extent to which our medical schools have complied with these recommendations, I sent a questionnaire to the deans or the professors of ophthalmology of schools ranked in Class A plus, and A, as given in The Journal, Jan. 18, 1913. These questions included:

1. The year for preliminary instruction and position of the instructor.
2. Whether or not didactic instruction is given.
3. The time and extent of section teaching.
4. Elective courses.
5. Facilities for postgraduate work.

There are sixty medical schools classified as above, and up to the time I was compelled to prepare this paper, replies had been received from thirty-six. Probably a larger number would not materially affect conclusions.

All of the replies state that some instruction is given in anatomy and physiology, and in all but two of the schools prior to the teaching of ophthalmology. It is impossible to judge of the extent of this teaching. Evidently it ranges from mere presentation of gross anatomy to sectional laboratory instruction in both anatomy and physiology. Instructors are the professors of anatomy and physiology or their assistants in twenty-eight schools. In most schools this instruction is subsequently reviewed by the professor of ophthalmology. In four schools only the professor of anatomy is concerned, no mention being made of physiology. In two preliminary teaching is left to the physiologic department, and in two more it is given by the professor of ophthalmology in the first or second year. The time given to this preliminary instruction is:

First year only	4 schools
First and second years	16 schools
First, second and third years	1 school
Second only	10 schools
Second and third	2 schools
Third only	3 schools
	—
Total	36 schools

The time relation between preliminary instruction and ophthalmology is:

According to recommendations of committee (i. e., in two successive years)	17 schools
One year between preliminary instruction and ophthalmology	11 schools
Two years between preliminary instruction and ophthalmology	6 schools
Two departments begin together in third year	1 school
Two departments begin together in second year	1 school
	—
Total	36 schools

It thus appears that but one less than half of the schools heard from have adopted the plan of successive years; evidently there is a general tendency to follow the committee's advice. All of the eleven schools with a single year intervening end preliminary instruction in the second, and give ophthalmology in the fourth year. This is doubtless due to the crowded nature of the third year. Three schools attain the "successive" idea by giving special anatomy and physiology in the last part of the third year—a good idea if the chief course is put in the fourth, and if the third year affords time.

My second question had reference to didactic teaching. Evidently there is no stampede to do away with the old method. There seems to be some tendency to depart from lectures and to substitute reading, quizzes on this reading really taking the form of "conferences," "round-the-table talks," etc. The fourth year is still selected by the large majority of schools for didactic instruction. In my judgment this work should be put into the third year, when feasible, because it will receive more thought if introduced before the exigencies of graduation present themselves. Six schools neglect the didactic course entirely, or give it in a modified form. The character and standing of these schools make this tendency important. The University of Colorado, for instance, makes laboratory instruction a prominent feature of its didactic work. The University of California limits its didactic instruction to "a few lectures in the third or fourth year." Leland Stanford Junior University confines it to "association with clinical cases in the senior year." The reply from Cornell University states that didactic lectures illustrated by lantern-slides are given to the fourth-year students; the number of lectures is not stated. Evidently it is small. In Columbia, didactic teaching, if it can be so called, is limited to one clinical lecture a week for one-half year. The Johns Hopkins University gives no didactic teaching, apart from explanations in its clinical work, until the fourth year; then didactic lectures are elective. Required instruction in this university consists of ophthalmoscopy for two or three weeks in the second year and clinical demonstration daily for six weeks in the fourth year. The Iowa State University, the last of those showing a tendency to give up didactic teaching, seems to occupy a position of its own. A personal letter from Professor Dean illustrates how he has hypnotized the authorities of the university and obtained about all that one should desire—maybe a little more. He says:

> In the fourth year . . . about 50 per cent. of their time is devoted to ophthalmology. Throughout the fourth year the class as a whole receives two and one-half hours per week of instruction. This consists of clinical lectures illustrated by cases. Following the lectures the students see the cases, each case being then in charge of a separate demonstrator. The class is divided into three sections. Each section receives the following work for one-third of the year: three hours per

> week of outclinic service; three hours per week of operative service; two hours per week of ward class work. During this time each student has at least six bed-patients under his personal observation.

In addition to this undergraduate work, Dr. Dean has at his disposal three salaried positions to which he can appoint graduates.

The wisdom of departing from didactic teaching is certainly questionable. It has to be decided according to the opportunities and environment at each school. Also the class of students is a factor. A good teacher, with students well grounded in anatomy, physiology and the principles of pathology, can no doubt save time and give more valuable instruction with the patient before him. On the other hand, there is a certain numerous class of students who will better understand what they see if they know previously what they are to look for, and on what symptoms and signs depend. Retaining or abandoning didactic teaching must be a local issue; but it is evident that there is a tendency to discredit it.

Section teaching is reported from every school. The preference is for the fourth year—twenty-five schools. In one school it is confined in the third year; in eight others it is divided between the third and fourth; and in two the year is not given—probably the fourth. A rather striking reply is from Cornell University; section teaching is limited to eighteen hours in the last term of the fourth year, a period, it seems to me, entirely too late to begin such work. Some of the larger universities have a certain number of beds set apart for eye patients; these are used in section instruction. It would seem that at least a beginning has been made toward providing such instruction as will lay a proper foundation for postgraduate work. The time devoted to section teaching varies from ten to forty-six hours per section. Comparing some of the reports with the catalogues, it is obvious that a practical difficulty in section teaching is obtaining a sufficient number of capable instructors. In some of the schools large classes have to receive this instruction from the professor of ophthalmology with one or two assistants. It is impossible with such inadequate force to meet the requirements of twenty hours' section teaching for each student.

As to elective courses, replies from twelve schools state definitely that there are none. Ten others recite clinical opportunities at general and special hospitals of which the student may avail himself if he so desires, but this is a matter of volition. In fourteen schools there exists some sort of an elective system. In seven of these it is limited to ophthalmoscopy and refraction. In one the student is allowed to elect ophthalmology, and if he so desires "spend all his time in this work." In but four of the thirty-six schools from which I received replies does there seem to be attempt to give elective courses in all departments. These are Johns Hopkins University, University of Colorado, Harvard and the University of Pennsylvania. The University of Iowa should probably be added to this list on account of the large scope of its work. The remaining school which reports an elective course is the Rush Medical College. I have placed it alone, because, coming as it does from so thoughtful a teacher as Dr. Wilder, it merits consideration as a standard for elective work. The course includes advanced work in anatomy, pathology and bacteriology of the eye, with courses in refraction. It seems to me that this limitation is wise. If the standards of ophthalmologic teaching and practice are ever to be elevated, the four subjects to which Dr. Wilder limits his elective courses must be the foundation. Unless men are tied up to these subjects, with, of course, needed clinical illustrations, they will not, save in rare instances, give them the necessary attention.

An interesting fact brought out by the replies is the small importance which teachers are attaching to operative courses for undergraduates. In but two schools are they compulsory, the Jefferson Medical College and the Medico-Chirurgical College. In the latter each student does six different operations on pigs' eyes. In two schools, Johns Hopkins University and the University of Michigan, operative work is elective. Reference is made in some of the replies to facilities for operating on animals' eyes if students so desire; but they are not encouraged to do so.

The Section has very recently heard about such postgraduate work as exists. The Universities of Pennsylvania and Minnesota are apparently earnestly engaged in organizing it on a scientific basis. Dr. Jackson's work in Denver is well known. The University of Iowa seems to have made real headway; Tulane University reports adequate opportunities for postgraduate hospital work, and Harvard has an organized course. Dr. Wilder, at Rush, offers what is essentially a continuation of the elective course to undergraduates. He says "facilities for postgraduate work embrace courses in pathology, anatomy, refraction work in the dispensary and at the hospital clinics." Three of my correspondents were good enough to outline their ideas of postgraduate work. For instance, Dr. Todd thinks that two years at least should be given to it; the first, as an intern in a hospital with time devoted to laboratory study, the second as an instructor and assistant in operative work; this, he thinks, should be followed by a year abroad. Dr. Jackson is in accord with Dr. Wilder regarding the necessity of strictly scientific branches; so, evidently, are many others.

It is impossible to divorce undergraduate work from postgraduate work. We recognize that a student cannot be made a competent ophthalmologist at graduation by any system available. But behind this truth there has lurked a tendency to reduce special teaching to what has been termed "essentials"; in other words, to attempt nothing more than teaching diagnosis of common diseases and how to avoid dangerous blunders. It will be hard to do more: *method of teaching this* is the important question.
